Finally, patient-related considerations should also be taken into account for decision-making. In patients undergoing minor surgical procedures with a low risk for infection, continuing treatment through the perioperative period may be reasonable. However, other patient-specific characteristics such as diabetes or chronic corticosteroid use would argue for adherence to the aforementioned guidelines. A more in-depth and current appraisal of these considerations has been published.¹³²

The integument

Skin integrity may be compromised before and after procedures in patients undergoing orthopedic surgery because of chronic therapy (i.e., corticosteroids, immunosuppressive agents) or as a manifestation (i.e., decubitus

ulceration) of the underlying disease or orthopedic condition. In addition, delayed wound healing and a propensity for infection may result from these influences. Initiating preventive measures early to combat the development of decubitus ulcers (particularly of the heels and buttocks) is vital for an uncomplicated postoperative course.

The eye

Patients taking chronic optic medication should have their eye drops instilled before surgery, especially for prolonged procedures. The one exception is the use of phosphodiesterase inhibitors for the treatment of glaucoma because these agents may prolong the action of the neuromuscular blocker succinylcholine. This is particularly pertinent in patients with Sjögren syndrome, who require artificial tears to prevent perioperative conjunctival injury.

Patients in the prone position are at risk for ocular injury secondary to external pressure, and those with underlying vasculitis of the optic vessels are at particular risk for ischemic injury to the eye. The anesthesiologist must take particular care in these cases to position the patient carefully to avoid excessive pressure on the eye and provide appropriate eye protection.

REGIONAL AND WIDESPREAD PAIN

71

Neck pain

■ LES BARNSELEY

- Neck pain is common regional pain syndrome that usually arises from an undefined mechanical or musculoskeletal disturbance.
- It occurs acutely and is associated with marked hypomobility.
- Chronic symptoms are poorly understood.
- Neck pain may be a manifestation of a serious underlying malignant, infectious, or inflammatory disorder.
- It can occur in association with neurologic involvement—myelopathy and radiculopathy.
- No examination or imaging findings are known that can reliably identify the source of neck pain.
- It may be investigated with techniques targeting the pain.

INTRODUCTION

The neck provides a link of great flexibility between the sensory platform of the head and the trunk. Simultaneously, it provides vital conduits for neural and vascular tissue between the brain and the rest of the body. These conflicting priorities are achieved through the structure of the cervical spine, which combines strength with an extraordinary range of movement. Strength is achieved through a bony tube made up of the individual vertebrae. Range of movement is achieved through a complex articular system involving ligamentous intervertebral disks and paired posterior zygapophyseal joints in the lower part of the neck and loosely constrained synovial joints at the upper levels. The disks fissure posteriorly as part of the normal aging process,¹ thereby permitting rotatory movement through an oblique axis.² The posterior zygapophyseal joints have no bony constraint, which facilitates a broad range of movement that involves gliding of flat surfaces in concert to permit flexion and extension and in opposite directions to produce rotation. This complex is subject to almost constant activity, with the neck being reported to move more than 600 times per hour or once every 6 seconds.¹

Pain perceived in the region of the neck encompasses local sources of pain among the intrinsic structures of the cervical spine and distant sources that refer pain to the neck. Though previously thought to be acute and self-limited, contemporary reviews suggest that a chronic relapsing pattern is more typical.³ Most instances of chronic neck pain will prove to be musculoskeletal in origin, but it is incumbent on the physician to exclude other serious and potentially treatable pathology. Fortunately, the history and physical examination typically permit ready differentiation of musculoskeletal from other causes of neck pain. Once non-mechanical-related conditions have been excluded, the second responsibility is to provide a diagnosis of the structure and pathology producing the neck pain. Only with a sound anatomic diagnosis can therapy be targeted and rational.

Frequently discussed in association with neck pain but really a separate problem is the question of cervical nerve root or cervical cord compression.

These problems warrant assessment on their own merit, independent of any associated neck pain, and are considered later.

EPIDEMIOLOGY

Incidence, prevalence, and risk factors

Though less common than low back pain, neck pain is a common human experience—its universality and unpleasantness are reflected by colloquial use of the term “pain in the neck” to describe a particularly disagreeable circumstance or individual. A comprehensive review of the epidemiology of neck pain revealed an incidence between 10% and 21% and a mean 1-year prevalence of 25.8%.³

The determinants of chronic, mechanical neck pain are still incompletely studied. There is no doubt that trauma, particularly whiplash injury, is an important contributor to the burden of chronic neck pain. A clear relationship has been demonstrated between the nature of an occupation and neck pain, with manual workers having higher frequencies of neck pain than those with sedentary jobs.⁴ Other positive associations with neck pain include a self-reported heavy workload, level of education, and depression. Chronic neck pain has also been associated with metabolic syndrome and a high body mass index.^{5,6} A longitudinal study of adolescents demonstrated that dynamic loading sports involving the upper limbs during adolescence were associated with a 40% reduction in risk for the development of neck and shoulder pain 7 years later but that psychosomatic symptoms were associated with up to a 10% increase in risk. Increased flexibility in adolescent boys has been shown to be protective of later neck symptoms in males, whereas in girls good endurance strength confers similar benefit.⁷ One of the strongest predictors of future neck and shoulder pain was frequent symptoms of neck and shoulder pain during adolescence.⁸ Neck pain also has substantial genetic components, with a twin study suggesting heritability in the range of 35% to 58%.

Natural history

Neck pain is divided arbitrarily into acute pain, which lasts less than 3 months, and chronic pain, which lasts longer than 3 months. For a given episode of acute neck pain, only 40% of patients will either recover fully or have mild symptoms.⁹

Chronic neck pain is weakly predicted by the concomitant presence of low back pain, older age, previous episodes of neck pain, and stable symptoms for 2 weeks before the assessment.

PATHOGENESIS OF NECK PAIN

The exact cause of most mechanical neck pain remains elusive. In the case of acute neck pain, it has been suggested that the pain and hypomobility may stem from entrapment of the intraarticular menisci of the cervical

zygapophyseal joint in the large capsular recesses of these joints, with inflammation, pain, and stiffness ensuing before the meniscus is “reduced.”¹⁰

The source of more chronic neck pain remains arcane. The pathologic data concerning necks focus on problems that lead to neurologic compromise. The use of techniques such as zygapophyseal joint blocks enables, at a minimum, the anatomic source of the pain to be detected in a significant proportion of cases. In the case of the disk, annular tears extending into the innervated outer third of the disk may well be the source of the pain, but why the normal age-related changes, including extensive posterolateral fissuring, fail to cause pain in a significant proportion of patients is not understood.¹¹ A variety of lesions resulting from trauma to the neck could affect the cervical zygapophyseal joints (see later). Many of these lesions could result in premature osteoarthritic changes, which can be expected to be painful. Alternatively, intraarticular adhesions, capsulitis (analogous to frozen shoulder), or ongoing synovitis may be responsible for chronic zygapophyseal joint pain. A broader view of neck pain should also incorporate the possibility that some chronic neck pain is a centrally mediated or multifactorial problem that represents a complex interplay between biologic, psychological, and social factors—the so-called biopsychosocial model. As discussed in Chapter 24, pain is recognized as a phenomenon arising from nociceptive excitation perceived in a psychological and social milieu. It is generally accepted that pain, particularly chronic pain, is frequently associated with impaired social functioning and psychological distress. It is therefore difficult to separate causative from incidental relationships. It has been noted that when chronic neck pain has been fully relieved, evidence of psychological distress disappears,¹² thus implying that in this highly selected group, psychological distress was a consequence rather than cause of the chronic pain.

CLINICAL ASSESSMENT

History

Neck pain may be classified as being referred from distant (noncervical) structures; as arising through involvement of cervical structures by neoplastic, inflammatory, or infectious disease; or as being mechanical or musculoskeletal in origin. Diseases that may refer pain to the neck are outlined in Table 71.1. Fortunately, these conditions usually have other clinical characteristics, such as exertion-induced pain with angina, thus highlighting the need to take a complete history. Table 71.2 considers conditions that can affect components of the cervical spine. The clinical history should cover characteristics of the pain outlined in Box 71.1 to facilitate detection of more serious conditions.

Onset of pain

The circumstances surrounding the onset of pain are helpful in suspecting a diagnosis of non-mechanical-related neck pain. Older age or a past history of malignancy, particularly of the lung, breast, prostate, thyroid, or kidney, should raise the possibility of metastatic bone disease. Previous surgery, immunosuppression, and past infections increase the risk for hematogenous osteomyelitis or septic arthritis. Inflammatory conditions such as ankylosing spondylitis, rheumatoid arthritis (RA), and polymyalgia rheumatica are suggested by involvement of areas other than the cervical spine, a history of pain and stiffness on first rising and after immobility (“gelling”), and systemic features such as weight loss or sweats.

Musculoskeletal pain typically arises following trauma or unaccustomed activity, and intrinsic disease processes, such as osteoarthritis, may be responsible for the spontaneous development of pain.

Quality of pain

The pain associated with mechanical musculoskeletal derangement is typically dull, deep, and aching. Exacerbations usually consist of short-lived sharp pains superimposed on the chronic symptoms. Pain that does not follow this pattern, for instance, pain that is shooting or electrical, should raise suspicion that neural structures are involved. Deep, unremitting pain is a sinister sign implying ongoing distention, deformation, or invasion of pain-sensitive structures, which may occur with malignancy.

Frequency and duration of episodes of pain

Mechanical or noninflammatory musculoskeletal pain is typically experienced in episodes that are related to movement and exertion. The pain is made worse by particular postures or exercises and is characteristically improved by rest and immobility. Pain that does not follow this pattern, that is, not altered by movement and worsens spontaneously, suggests a more sinister underlying cause.

Site, radiation, and source of pain

Musculoskeletal cervical pain is typically perceived over the posterior aspect of the neck and rarely radiates past the anterior border of the sternomastoid muscle. Pain in the anterior part of the neck usually indicates disease in one of the anterior structures (see Table 71.1). Intrinsic neck pain can radiate into the head and down onto the shoulders. Headache is particularly common in patients with upper cervical pathology, particularly at C3 and above. Pain from structures at these levels is often perceived in the distribution of the first division of the trigeminal nerve, or the back of the head and neck, and pain from lower cervical levels can be referred to the shoulder girdle, arm, interscapular region, and chest wall. It has been observed that the more severe the pain, the larger the area of referral.

The clinical history and examination do not allow a specific anatomic structure to be impugned as a source of the pain. However, studies of normal individuals have demonstrated patterns of pain referral stemming from noxious stimulation of cervical structures. Probing the anterior part of the cervical disks in awake subjects produced pain in the posterior aspect of the neck several segments below the level stimulated (Fig. 71.1a).¹³ Feinstein and associates¹⁴ revealed that injections of hypertonic saline into the deep cervical muscles produced distinct patterns of pain, again over the posterior aspect of the neck (see Fig. 71.1b). Dwyer and colleagues¹⁵ distended the capsules of the cervical zygapophyseal joints (C2-3 to C6-7) of normal volunteers. Each joint had a reproducible and characteristic pattern of pain referral (see Fig. 71.1c). Similar methodology was used by Dreyfus and coworkers to investigate referral patterns of pain from the atlantoaxial joint (AAJ) and the atlantooccipital joint (AOJ).¹⁶ Injecting these joints in normal volunteers produced pain in the suboccipital region (see Fig. 71.1d). There is extensive overlap between different structures and the same structure at adjacent levels. In particular, the upper cervical zygapophyseal joints and the AAJ and AOJ all refer pain to the suboccipital region.

Consequently, it is impossible to determine the site of origin of neck pain on the basis of the site of pain alone. The approximate level of involvement may be determined, but not the structure. Furthermore, a single source of pain may produce pain over a wide area through the enhanced receptive fields of spinal neurons such that the pain may appear diffuse and unfocused.

Pain can be referred to the neck from other musculoskeletal structures. In similar experiments on normal volunteers, injection of hypertonic saline solution into the acromioclavicular¹⁷ and sternoclavicular¹⁸ joints frequently produced pain in the neck, sometimes with little local discomfort over the target joint.

Associated features

Infections are typically accompanied by fever and malaise, as well as by specific features reflecting the tissues involved. Pain arising from malignant disease may be accompanied by paraneoplastic conditions such as peripheral neuropathy, hypercalcemia, or features of metastatic disease elsewhere.

Neurologic abnormalities

Neurologic symptoms such as paresthesia and subjective weakness may occur in patients with neck pain. Their significance depends on whether

PATTERNS OF PAIN ELICITED BY NOXIOUS STIMULATION OF DIFFERENT PARTS OF THE CERVICAL SPINE

they are accompanied by definite neurologic signs. Weakness in the absence of neurologic signs may seem to suggest a nonorganic basis for the complaints, but experimental studies have shown that pain has an inhibitory effect on motor neuron pools that results in a greater demand for effort and a consequent, subjective sensation of weakness. Paresthesia suggestive of nerve root irritation may arise as a result of functional thoracic outlet syndrome caused by spasm of the scalene muscle. Alterations in sensation have been described in patients with chronic pain states; such alterations take place as a result of complex interactions between nociceptive and other sensory pathways and lead to reports of altered sensation that do not correspond to the classic dermatomal or peripheral nerve distributions.

Hard neurologic signs are uncommon findings in patients whose primary complaint is neck pain, but if detected, the thrust of the investigation is to determine the site and nature of the lesion. Coexistent neck pain and neurologic deficit may be due to intrinsic involvement of the cord, dura, or nerve roots by neoplasia or infection (see Table 71.2) or to compression of neural tissue by bone or disks, which are themselves possible sources of pain. Clinical assessment should establish whether the spinal cord, nerve roots, or both are affected. The unexplained onset or presence of impaired sphincter function, lower limb weakness, and a sensory level is indicative of cord compression and demands urgent assessment, ideally by magnetic resonance imaging (MRI), to determine whether a reversible cause is present.

Signs of nerve root pathology, such as loss of a reflex, dermatomal sensory loss, or myotomal motor weakness (Fig. 71.2), may require confirmation by nerve conduction studies. Cross-sectional imaging often demonstrates the site and nature of the lesion and helps ascertain whether the problem is intrinsic disease of the nerve or external compression. These investigations are not justified for neck pain alone in the absence of neurologic signs.

Clinical examination

The principal role of the clinical examination in the setting of neck pain is to exclude other conditions contributing to the pain, such as infection, malignancy, or inflammatory arthropathy, or to exclude neurologic involvement. Once a diagnosis of mechanical neck pain is made, the diagnostic utility of clinical examination of the neck is limited.

General examination

A general examination is performed to exclude non-mechanical-related causes of neck pain. It should be particularly focused on any system or systems in which abnormalities have been suggested by the history. In addition, examination of temperature, skin, joints, lymph nodes, abdomen, and breasts should be performed. The yield from such assessment in the setting

of neck pain is not known and probably low, but the serious consequences of missing a potentially treatable systemic illness, malignancy or infection make performance of such an examination crucial. Inspection and palpation of cervical structures such as the thyroid, carotid arteries, and lymph nodes are indicated to exclude non-musculoskeletal-related conditions.

The neck should be examined for tenderness, which is best achieved by exerting pressure first on a control area such as the occipital protuberance. This pressure should then be applied along the spinous processes and then the articular pillars, as well as the trapezius muscles. This provides some standardization of the stimulus and permits some grading of response. Unfortunately, localization of the tenderness contributes little in the way of diagnostic information. No correlation has been demonstrated between tenderness in a particular area and a specific anatomic diagnosis.

Neurologic examination

The aims of neurologic examination in the setting of neck pain are to exclude cervical nerve root lesions (see later) or spinal cord lesions. The former requires detailed examination of the arms, including assessment of power, tone, reflexes, and sensory function. The lower limbs should be examined similarly, with the principal aim being exclusion of any upper motor neuron signs indicative of cord compression from the painful lesion in the neck.

Neck movement

Examination of the neck traditionally incorporates documentation of active and passive range of movement. However, basic research casts grave doubt on the diagnostic utility and reliability of such assessments. The detailed cineradiographic techniques used by Van Mameren and associates¹⁹ to assess flexion and extension have revealed that even normal individuals display marked variation in the pattern and amplitude of both segmental and total range of neck movement on different occasions. Therefore, only gross abnormalities in range of motion, such as reproducible asymmetry of movement, are likely to be assessed reliably. Furthermore, the clinical utility of assessment of neck movement is open to serious question. Biomechanical studies have shown that 50% of cervical rotation takes place at the AAJs.²⁰ The remaining rotation occurs in approximately equal proportions below C2 such that each segment contributes less than 7 degrees of movement. Consequently, even complete fusion of a segment below C1-2 may be clinically undetectable and will most likely fall within measurement error. At the same time it is conceivable that a painful lesion in the neck below C1-2 may produce marked loss of movement, in excess of 50% of range of motion, as a result of pain, fear of pain being produced, or local muscle spasm secondary to pain. At best, restriction of movement in the neck is indicative of one or more of the following: disturbance in neuromuscular control of the neck, a painful lesion aggravated by movement, or mechanical restriction

CERVICAL ROOT LESIONS

		T1	Finger abduction Thumb adduction/ opposition

Fig. 71.2 Sensory and motor distribution of the cervical roots.

anywhere in the complex articular arrangements between two or more vertebrae.

CERVICAL NERVE ROOT COMPRESSION

Although it may not be a cause of neck pain, cervical nerve root compression is included here because suspicion of its presence dictates subsequent investigation.

Clinical features

Pain arising from overt compression or disease of the nerve root typically follows the appropriate dermatome and is therefore felt in the arm and not the neck. This pain will typically be radicular in quality, that is, pain that is perceived in a narrow band on the skin of the arm and that has electrical, radiating, or shooting properties. However, more somatic (i.e., deep, diffuse, aching) pain in proximal structures can be produced by nerve root compression.²¹ At the same time, pain that is perceived in the forearm or hand is unlikely to be somatic referred pain and more likely to be radicular in origin. Pain may be accompanied by neurologic symptoms such as numbness, paresthesia, altered sensation, and motor weakness. Pain may be perceived across the top of the shoulder from lesions involving C4 and in the face and head from lesions affecting C2 and C3. However, these levels are uncommonly affected, so much so that isolated lesions at these levels should prompt a systematic search for sinister, space-occupying pathology. The majority of cervical root lesions occur at C6, C7, and C8 and typically produce symptoms in the forearm and hand (see Fig. 71.2). Because of the extensive overlap of dermatomes in the arm and the complex central representation of the upper limb, pain referred to the arm from root irritation may be more diffuse than the traditional diagrams of dermatomes would suggest.

Unlike the lumbar spine, disk prolapse itself is not the predominant cause of cervical nerve root irritation. The nerve roots in the lower cervical spine lie in the inferior part of the foramina, at or below the level of the disk, and are susceptible to compromise by osteophytic involvement from the adjacent uncinate process or adjacent zygapophyseal joint.¹ Discogenic neural encroachment in the cervical spine is typically due to discrete fragments of the disk that herniate into the foramen.

Clinical examination

Supplementing the neurologic assessment described earlier, the most specific clinical test for nerve root entrapment is the compression or Spurling test. The patient's neck is moved passively into extension and rotated to the symptomatic side. Axial pressure is then applied to the neck by the examiner. This series of movements has been shown to narrow the intervertebral foramina. If the patient's radicular symptoms are reproduced, the test is positive.²² This test has good interrater reliability and is highly specific but relatively insensitive. The combination of a positive compression test and abnormal neurologic signs in the arm is strongly predictive of nerve root compression.

INVESTIGATIONS

Imaging

Radiographs

Plain radiographs of the cervical spine may be appropriate in patients with a history suggestive of severe trauma that is likely to produce fracture or severe subluxation or when major instability is suspected. The most useful views in these circumstances are lateral flexion and extension views, open-mouth views, and to a lesser extent, the anteroposterior view. To assess for subluxation, lines linking the anterior vertebral bodies, posterior vertebral bodies, and posterior border of the intervertebral canal on a lateral projection are constructed. These lines should describe a smooth arc (Fig. 71.3). The presence of a "step" in this arc is a sign of subluxation caused by either retrolisthesis or spondylolisthesis. Gross abnormalities in motion may be detected by comparing flexion and extension views, and instability can be demonstrated by comparing the construction lines described earlier on flexion and extension views. Of particular note is the issue of atlantoaxial instability. This is typically seen with RA but can occur in the presence of other destructive lesions affecting the odontoid peg or the transverse or alar ligament complex. It is assessed by comparing the gap between the anterior part of the odontoid peg and the posterior margin of the anterior arch of

Fig. 71.3 Plain lateral radiograph of a normal cervical spine. Lines joining the anterior part of the vertebral body (a), the posterior aspect of the vertebral body (b), and the anterior border of the laminae (c) should describe a smooth arc.

the atlas as seen on lateral flexion and extension views. The gap should normally be less than 5 mm (see Chapter 40).

Plain radiographs may also be useful in excluding primary bone disorders such as Paget disease, significant sclerotic malignant infiltration of bone, and destructive lesions such as osteomyelitis. However, standard views of the cervical spine are complex images with many structures being superimposed on all views. Consequently, radiographs are insensitive in detecting small abnormalities, such as purely lytic lesions without significant cortical bone destruction. When such lesions are suspected but not detected on plain films, further imaging with computed tomography (CT), MRI, or nuclear medicine techniques is desirable.

For patients with mechanical pain, the value of plain radiographs is much more limited. It has repeatedly been demonstrated that the presence of degenerative or spondylitic changes in the spine does not correlate with symptoms of neck pain. Friedenber and Miller studied the plain radiographs of 92 pairs of age- and sex-matched patients with and without neck pain.²³ The incidence of degenerative changes rose with age; was most common at the C5-6 level, at both the intervertebral disk and the zygapophyseal joints; but bore no relationship to the presence of neck pain.

Computed tomography

The principal value of CT in the assessment of cervical lesions is visualization of the bony conduits through which neural tissue passes. CT is of less value in assessing soft tissue. For neck pain alone without neurologic symptoms or signs and without clinical or plain radiographic evidence of a non-mechanical-related disorder, CT scans are not indicated.

Magnetic resonance imaging

MRI is highly specific and sensitive for disk herniations when compared with surgical findings (Fig. 71.4). It is particularly helpful in visualizing neural and soft tissue structures and intracord pathology in the cervical region (such as demyelination, intraaxial tumors, and spinal cord infarction) and enables accurate appraisal of developmental defects such as the Arnold-Chiari malformation. However, for assessment of neck pain of mechanical origin, MRI, like CT, has not been validated. It has been shown that nearly a fifth of all asymptomatic patients have abnormalities on MRI, with 60% of older patients having abnormalities of their intervertebral disks.²⁴ MRI should be reserved for patients in whom intraspinal pathology, neural compromise, or another neurologic disorder is clinically suspected.

Isotope scans

Bone scanning with technetium-labeled methylene diphosphonate (^{99m}Tc-MDP) is highly sensitive for the detection of bony pathology, with the notable exception of lesions that have a purely lytic pathology, particularly multiple myeloma (Fig. 71.5). However, for tumors that most commonly

Fig. 71.4 Disk herniation on magnetic resonance imaging (MRI). Axial (a) and sagittal (b) MRI scans of a 47-year-old man with neck pain, decreased left biceps jerk, and numbness over his thumb after a motor vehicle accident demonstrate a significant left posterolateral disk protrusion at C5-6 that is significantly compromising the exiting C6 nerve root.

Fig. 71.5 Myeloma detected on a computed tomography scan of a 63-year-old man with known multiple myeloma in whom neck pain developed. Plain radiographs and a bone scan failed to demonstrate the osteolytic lesions affecting the odontoid peg.

metastasize to bone—lung, breast, prostate, thyroid, and kidney—bone scanning is the investigation of choice for the early detection of metastases. It may also be useful in the detection of infection, for which it shows avid uptake in the affected region. With early angiographic assessment during injection of the radiopharmaceutical and a blood pool image a short time later, increased vascularity can be assessed, which can help differentiate infection or inflammation from degenerative changes, where later bone-phase scans show uptake. Notable in the cervical spine is the normal, physiologically greater uptake over the C2 spinous process than over the lower cervical vertebrae. Anatomic localization can be facilitated with co-registered CT scanning.

Blood tests

Blood tests are indicated only when problems such as tumor or infection are suspected. The most useful investigations would be a complete blood count, erythrocyte sedimentation rate (ESR) or C-reactive protein (or both), and serum alkaline phosphatase. Infection and tumor are typically associated with an elevated ESR, infection with an elevated white blood cell count, and Paget disease with increased alkaline phosphatase. There is no evidence to advocate the use of these investigations for “screening.”

Investigations targeting pain

In the absence of reliable imaging correlates of mechanical neck pain it is necessary to target the pain itself to identify the painful structure. This can be accomplished either by stimulating a potentially painful structure and

Fig. 71.6 Arthrogram of the C2-3 zygapophyseal joint. A needle has been placed into the center of the joint, and injected contrast medium has filled the loose anterior and posterior recesses.

determining whether pain is produced or by anesthetizing a structure and determining whether the pain is relieved, thereby implicating that structure as a source of the pain.

Zygapophyseal joint blocks

Techniques for the diagnosis of cervical zygapophyseal joint pain rely on the principle that if a joint is a source of pain, anesthetizing that joint will relieve the pain. The cervical zygapophyseal joints can be anesthetized by injecting local anesthetic into the joint, or alternatively, the nerves that convey pain from the joint can be anesthetized.

Intraarticular blocks of the cervical zygapophyseal joints are performed under fluoroscopic control. A narrow-gauge spinal needle is directed toward the center of the target joint. Once the needle is felt to have pierced the joint capsule, a minimal volume of contrast medium must be injected to confirm intraarticular placement (Fig. 71.6). Thereafter, 0.7 to 1.0 mL of local anesthetic can be injected to anesthetize the joint.

The total volume injected should not exceed the capacity of the joint (generally accepted to be less than 1.0 mL) because distention beyond this volume may cause capsular rupture or extraarticular leakage, including epidural spread, which may compromise the specificity of an intraarticular block by anesthetizing structures other than the target joint.

Cervical medial branch blocks are a more expedient way to anesthetize a cervical zygapophyseal joint. They are easier to perform, are less painful to the patient, and provide the same diagnostic information.²⁵ They are performed under fluoroscopic control via either a posterior or lateral approach. These blocks take advantage of the anatomy of the nerve supply to the cervical zygapophyseal joints.

The cervical zygapophyseal joints are innervated by articular branches derived from the medial branches of the cervical dorsal rami. The C4-8 dorsal rami arise from their respective spinal nerves just outside the intervertebral foramina and pass dorsally over the roots of the transverse processes. The medial branches of the typical cervical dorsal rami course posteriorly around the waist of the articular pillars and are covered by tendinous slips of the origin of the semispinalis capitis (Fig. 71.7). Ascending and descending articular branches arise near the posterior aspect of the pillar to supply the joints above and below (see Fig. 71.7). Consequently, each typical cervical zygapophyseal joint receives dual innervation, from the medial branch above and from the medial branch below. A joint can be anesthetized or denervated by blocking both these nerves. The C2/3 joint receives its innervation from the third occipital nerve, which is the superficial medial branch of C3. After supplying the C2/3 joint, it furnishes muscle branches to the semispinalis capitis and becomes cutaneous over the suboccipital region.

The cervical medial branches below the third occipital nerve, (i.e., C3-7) can be anesthetized reliably by placing a small amount (0.25 to 0.5 mL) of local anesthetic onto the nerve as it passes across the waist of the articular

Fig. 71.7 A posterolateral drawing of the cervical spine illustrates the course of the medial branches of the cervical dorsal rami. All muscles except the origins of the semispinalis capitis at C4 and C5 have been removed. The medial branches of the cervical dorsal rami are seen to course across the waist of the articular pillars. At C4 and C5 they are shown covered by the tendinous origins of the semispinalis capitis. Articular branches arise from each medial branch, on the posterior aspect of the articular pillar, to innervate the zygapophyseal joints above and below. The medial branches are well away from the ventral rami of the spinal nerves and the vertebral artery.

pillar. Under image intensifier control a needle is placed onto the centrod of the articular pillar, usually from a lateral approach (Fig. 71.8). The third occipital nerve is anesthetized by placing local anesthetic onto the nerve as it passes across the C2-3 joint, with three injections used to cover its more variable course (Fig. 71.9).

The value of blocks as a diagnostic tool depends on correct interpretation of the patient's responses. Diagnoses based on a single block are compromised by a false-positive rate of between 27% and 45%.²⁶ To circumvent this problem, two blocks should be used, be administered on different occasions, involve anesthetics with different durations of action, and be delivered in random order under double-blind conditions. The veracity of the response is then adjudicated by the patient's report of the duration of pain relief afforded by the anesthetic given. Because the medial branches below the third occipital nerve do not have reliable cutaneous representation, the only way that a patient can tell which anesthetic was used is through the duration of pain relief. This approach has been formally tested and found to be a valid means of identifying cervical zygapophyseal joint pain.²⁷ A refinement of this process is the addition of a third, placebo injection with normal saline used as the injectant, which increases the sensitivity of the technique; any response to an anesthetic with no response to the saline is accepted as a positive test.

Studies using these techniques attest to a prevalence of cervical zygapophyseal joint pain of 54% in patients with chronic neck pain (whiplash) after motor vehicle accidents²⁸ and between 36% and 55% in less selected patients.^{29,30}

Other anesthetic blocks

Anesthetic blocks of other structures, such as the greater occipital nerve and ventral rami of the spinal nerves, may be useful in confirming or eliminating structures in their territories as causes of the pain, but in contrast to zygapophyseal joint blocks, these procedures do not have documented reliability, sensitivity, and specificity.

Provocation diskography

The only regularly used provocative test in the neck is provocation cervical diskography, in which a disk is punctured by a needle and distended by injecting contrast medium. A positive diskogram occurs when the procedure reproduces the patient's usual pain and implicates that disk as the source of the pain.³¹ The response can occasionally be confirmed by injecting local anesthetic in an attempt to abolish the pain. In practice the procedure itself can be quite painful, and it is often difficult for patients to judge whether it is their usual pain that is being reproduced. Furthermore, in a significant proportion of patients the pain reproduced by diskography can be eliminated completely by subsequent zygapophyseal joint blocks at that level,³² thus indicating a significant false-positive rate. On the basis of current evidence, diskograms should be considered true positives only if zygapophyseal joint blocks at that level are negative (i.e., no pain relief). The side effects of diskography have been assessed in an audit study in a single practice, which revealed the rate of diskitis to be 0.16% per injection.³³

TREATMENT—NECK PAIN

Treatment of neck pain secondary to infection, tumor, or inflammatory disease such as RA is necessarily treatment of the underlying disorder and is not further considered in this chapter. Treatment of mechanical neck pain can be divided into treatments that are not targeted at any particular structure and are therefore nonspecific and those that are targeted at a particular painful structure within the neck. The aim of treatment is to relieve pain and thereby improve function.

Nonspecific treatments

Analgesics

The most commonly used nonspecific treatments of neck pain are simple analgesics such as acetaminophen (paracetamol). These agents have an important role in acute neck pain and can also be used safely over long periods for more chronic problems when other treatment is ineffective. In patients with more severe pain, synthetic and nonsynthetic opioids such as dextropropoxyphene or codeine can be used, but the potential for abuse and dependency needs to be considered before they are prescribed. These concerns should not prevent the physician from treating severe, refractory, and incapacitating pain appropriately. Sustained-release oxycodone taken for 4 weeks has been shown to be superior to placebo in patients with flare of chronic neck pain; it decreases pain and results in improvement in quality-of-life scales.³⁴ Refractory neck pain may respond to the use of pregabalin.

Exercises

Neck exercises aim to restore range of motion and strengthen the neck musculature. The rationale for the latter is reinforced by observations that females with chronic neck pain have a smaller cross-sectional area of the cervical multifidus muscles than do those without neck pain.³⁵ In women with chronic neck pain, high-intensity strength training has been demonstrated to be superior to range-of-motion exercises and stretching in the control of pain,³⁶ and other studies have shown strengthening and endurance exercises to improve quality of life.³⁷ Expert panel recommendations derived from comprehensive literature reviews advocate a useful role for exercise-based therapy,³⁸ and other reviews have found strong evidence supporting the effectiveness of strengthening and proprioceptive training exercises for frequent (i.e., recurrent acute) and chronic neck disorders.³⁹

Physical therapy

Physical therapy incorporates a number of potentially therapeutic modalities such as heat, cold, interferential therapy, laser, ultrasound, traction, and massage. The undoubted fact that patients report modest and temporary benefit with these approaches has provided a pragmatic basis for pursuing formal studies. Low-level laser therapy was shown to provide short-term benefit in a randomized controlled trial,⁴⁰ and a systematic review of acupuncture attested to a limited analgesic benefit over no treatment.⁴¹ The most recent systematic review of massage finds little data to support massage as an individual therapy. These observations are reflected in the findings of the

Fig. 71.8 (a) Radiograph illustrating a needle placed correctly for injection onto the medial branch of the C5 dorsal ramus. The target point is the centrod of the articular pillar as seen on a true lateral view. (b) Schematic diagram of medial branch blocks of the C4 and C5 dorsal rami to anesthetize the C4-5 zygapophyseal joint. Needles inserted from a lateral approach are positioned for infiltration of the medial branches of the cervical dorsal rami of C4 and C5. Note that the tips of the needles are proximal to the origins of the ascending and descending articular branches.

Fig. 71.9 Injecting the third occipital nerve. On a lateral radiograph of the cervical spine, arrows indicate the target points for injections to anesthetize the third occipital nerve and thus the C2-3 zygapophyseal joint. The points lie along a line that vertically bisects the articular pillar of C3 seen on a lateral projection. The middle point lies over the joint line, the upper point over the subchondral plate of the C2 inferior articular surface, and the lower point over the subchondral plate of the superior articular surface of C3.

best-evidence synthesis of the Bone and Joint decade 2000-2010 Task Force on Neck Pain and Its Associated Disorders, which supports acupuncture and low-level laser therapy for patients with neck pain not related to trauma.⁴²

Manual therapy/manipulation

A variety of “hands-on” techniques have been described for the treatment of neck pain. The best studied and most widely practiced are short-lever, high-velocity “adjustments,” usually described as manipulations and used principally by chiropractors. The other leading technique is known as mobilization and involves oscillatory movements through both the physiologic and accessory movements of spinal joints. The aim is to stretch the tight joint capsules of symptomatic joints. Studies to date have lumped all patients with neck pain together and have also often included lumbar pain. These studies show small benefit that is of uncertain clinical significance for manual techniques over conventional physical therapy modalities and best medical care.⁴³ The use of mobilization or manipulative techniques for acute pain may be expected to have a modest effect.⁴⁴ The most recent Cochrane review of this subject concluded that manipulation or mobilization may provide beneficial short-term or immediate change but that no long-term data are available.

Attempts to quantify the risks associated with cervical manipulation have concluded on the basis of a number of assumptions that the risk for death or serious injury was on the order of less than 1 per 500,000 to 1,000,000 manipulations.

Pillows and posture correction

Emerging data are correlating increased thoracic-to-cervical angles and anterior scapular rotation with neck pain. There are a paucity of reliable data showing that either “posture correction” or the use of variously profiled pillows helps patients with chronic neck pain. However, these are benign

interventions, and in the absence of proven efficacious treatment, their use may be justified. Modification of workplace environments and practices to decrease extreme movements of the neck and reduce the amount of time spent in a fixed cervical posture may be helpful for neck pain. Water-based pillows have been shown to decrease waking pain in patients with chronic neck pain.⁴⁵

Specific treatments

Zygapophyseal joints

With a definitive diagnosis of cervical zygapophyseal joint pain, therapy can be targeted at the specific joint. A randomized controlled trial of corticosteroid injected into painful cervical zygapophyseal joints after whiplash injury showed no benefit over injection of local anesthetic, with neither group obtaining useful relief.⁴⁶ It is not known whether patients whose pain arises spontaneously respond to intraarticular corticosteroids.

Cervical zygapophyseal joint pain can be controlled by denervation of the joint through percutaneous radiofrequency neurotomy of the medial branches of the cervical dorsal rami. A randomized controlled trial of this technique demonstrated prolonged relief of zygapophyseal joint pain (a median of 263 days vs. 8 days in the control group).⁴⁷ Similar results have been reproduced by other groups^{48,49} and by published audits of the author's practice. The long-term effects of denervating a cervical zygapophyseal joint are not known, but clinical experience with limited numbers of patients has indicated no lasting adverse effects, and the procedure can be repeated safely for recurrence of pain over a period of several years. Surgical intervention for proven cervical zygapophyseal joint pain has not yet been described.

Intervertebral disks

The treatment options for proven disk pain are limited. By virtue of their diffuse innervation, they cannot be selectively denervated to control pain in a manner analogous to that for the cervical zygapophyseal joints. Moreover, the exact site of pain production within a painful disk cannot yet be determined, so sclerosis or excision of particular disk components is not currently a viable option. Current practice for the treatment of suspected or proven cervical disk pain is cervical disk excision, usually with fusion. The rationale for this approach is simple—remove the part that hurts—but empirical efficacy studies on the effects of cervical spine surgery on neck pain are not available. The only studies available are open and nonrandomized and constitute retrospective reviews of individual practitioners' experiences.^{50,51} Randomized, controlled studies of this operation on patients with proven disk pain are needed. For the time being, physicians contemplating such invasive intervention should ensure that the diagnosis of cervical disk pain is sound and that the patient is made aware of the potential risks associated with such operations, as well as the uncertainty of response.

TREATMENT—CERVICAL NERVE ROOT COMPRESSION

Natural history

The majority of patients with cervical radicular pain will experience resolution of their pain over a period of a few weeks or months. Over prolonged periods of observation, less than 10% of patients have persistent moderate or severe disability.⁵²

Treatment modalities

Very few interventions have been shown unequivocally to be any better than others in the treatment of cervical nerve root pain. In particular, a three-armed, randomized study failed to show any long-term differences between cervical collar physiotherapy and surgery.⁵³ However, it would appear that any reasonable treatment is better than no intervention, with patients in the treated arms of trials reporting better satisfaction than those in placebo arms. Typical treatments that can be expected to increase patients' perception of improvement include physiotherapy, traction, transcutaneous electrical nerve stimulation, analgesics, and isometric exercises. These types of interventions can be applied with the understanding that this pain generally has a favorable natural history and that there is no evidence of superiority of any one intervention over any other. The choice therefore hinges on minimizing harm.

Corticosteroid injections

Corticosteroid injections into the epidural space, either via an interlaminar route or into the root sleeve, have been advocated for radicular pain. The

rationale is to decrease inflammation around the nerve root. No randomized trials of transforaminal corticosteroid injections have been performed, and the generally favorable natural history makes interpretation of the benefits noted in cohort studies nearly impossible. Any enthusiasm for the technique needs to be tempered with the knowledge that serious, fatal, and disabling outcomes have been reported from such injections that are thought to be due to occlusion of radicular vessels supplying the spinal cord.^{54,55} The frequency of these events is not known, but in a series of more than 500 injections, no serious adverse events were reported.⁵⁶ Notwithstanding this, the procedure is clearly accompanied by a material risk that anybody considering administering or receiving such treatment should consider.

Surgery

Surgery has the potential to relieve compression on the affected nerve root and should therefore be able to “cure” cervical radiculopathy and pain from cervical nerve root entrapment. However, this does not seem to always be the case. Marshaling the available empirical evidence suggests that in the acute setting, surgery is likely to improve symptoms faster than conservative measures can but without making any long-term difference when compared with conservative treatment. In the chronic arena, surgery is likely to improve symptoms in the majority of patients but is unlikely to effect a “cure.”⁵⁷ In the absence of a serious underlying cause of radiculopathy (e.g., tumor, infection), reasonable indications for surgery would include a progressive neurologic deficit or refractory and disabling pain.

WHIPLASH

Whiplash injuries warrant particular mention in any discussion of neck pain. Even though whiplash injuries are undoubtedly a common cause of acute neck pain, the frequency with which they cause chronic pain still spawns vigorous debate.

Biomechanics

Biomechanical studies have demonstrated that the traditional view of hyperextension being the primary event in whiplash is unduly simplistic. It has been found that axial compression and unnatural, double curvatures of the cervical spine are important and potentially damaging components of the cervical spine's response to inertial loading. Cadaver experiments have demonstrated that after rear-end impact, the lower cervical spine is thrust upward and forward.⁵⁸ The neck is therefore compressed from below. The lower cervical segments are extended while the upper segments are relatively flexed, which results in an S shape during the first 50 to 75 msec. Thereafter, all segments are progressively extended until the head is thrown forward. A more detailed cineradiographic study of normal volunteers described the motion of individual cervical segments during the extension phase of whiplash.⁵⁹ Following an 8-kph impact that resulted in 4-g acceleration, the C6 vertebra was driven upward. As it moved, the C6 vertebra extended underneath the rest of the cervical spine, which caused the higher segments to undergo a small initial flexion, of some 2 to 5 degrees in amplitude, before undergoing extension. The net result was that the cervical spine assumed an S shape at about 100 msec as the lower segments commenced extension while the higher segments were still undergoing initial flexion (Fig. 71.10). These movements took place around abnormal axes of rotation, with the pathologic axes being higher than normal. As a result the anterior end of the vertebra separated from the vertebral body below, and posteriorly the tip of the inferior articular process chiseled into the supporting superior articular process. Subsequently, the cervical spine underwent extension, as described in the classic model. These observations provide a biomechanical substrate for injuries to several structures in the spine, most notably the cervical zygapophyseal joints, which seem to be particularly susceptible to damage via uncontrolled rotation through abnormal axes.⁶⁰

Pathology

Our understanding of the pathology of whiplash has languished behind that of other spheres of rheumatology, primarily because of the paucity of pathologic material and the generally benign nature of the condition. However, the existence of a number of pathologic entities has been determined through clinical, animal, cadaveric, and postmortem studies,⁶¹ as summarized in Figure 71.11.

Plain radiographs have been shown to be profoundly insensitive to the detection of all but the most severe bony injuries of the cervical spine. Twenty-two cervical spines were harvested from patients who had died of head injuries.⁶² The specimens were then radiographed under optimal

Fig. 71.10 Appearance of sequential radiographs of the cervical spine during the extension phase of whiplash. At 110 msec the C5 vertebra rotates about an abnormally high axis of rotation, which causes the vertebral body to separate anteriorly from C6 and the inferior articular process of C5 to chisel into the superior articular process of C6. (Modified from Barnsley L, Lord SM, Bogduk N, Teasell RW, Shapiro A. *The pathophysiology of whiplash*. In: Malanga, editor. *Cervical flexion-extension/whiplash injuries*. Spine: state of the art reviews. Philadelphia: Hanley & Belfus; 1998, p. 209-42; and Kaneoka K, Ono K, Inami S, Yokoi N, Hayashi K, editors. *Human cervical spine kinematics during whiplash loading*. International Conference on New Frontiers in Biomechanical Engineering. Tokyo: 1997.)

conditions. Subsequent photographs of submillimeter slices revealed 245 injuries to various structures. Only four were detected on plain radiographs, even on second look.

Natural history

The natural history of whiplash is, for the most part, benign. Most patients recover within a few weeks of injury and have no residual symptoms. The main physical risk factor for chronic neck pain after whiplash is the severity of the initial symptoms.⁶³ A best-evidence synthesis has highlighted the role of psychological factors such as passive coping style, depressed mood, and fear of movement in slowing recovery.⁶⁴ It has been argued that the apparent differences in rates of chronicity of whiplash in different countries are evidence that chronic whiplash is a socially programmed phenomenon that pivots on the presence of a compensation system.⁶⁵ However, careful analysis of the data reveals that many of the studies proffered to support this view were compromised by small sample size, poor study design, and inappropriate endpoints such as insurance claims rather than clinical information.^{66,67} Follow-up studies of an inception cohort of patients assembled in the United Kingdom in the early 1980s revealed that most patients destined to improve do so within a few months, with very little improvement noted after 2 years. After 15 years, well after completion of any compensation, approximately 25% still had intrusive symptoms.⁶⁸

Treatment of acute whiplash injury

Treatment of acute whiplash is aimed at preventing chronicity, minimizing symptoms, and improving function. A review of conservative treatment of acute whiplash found that treatments such as cervical collars, rest, and passive physical modalities were generally inferior to programs involving

Fig. 71.11 AF, tear of the annulus fibrosus of the intervertebral disk; AL, tear of the anterior longitudinal ligament; AP, articular pillar fracture; AS, fracture involving the articular surface; EP, endplate avulsion and/or fracture; IM, contusion of the intraarticular meniscus of the zygapophyseal joint; SC, fracture of the subchondral plate; VB, vertebral body fracture; ZC, rupture or tear of the zygapophyseal joint capsule; ZH, hemarthrosis of the zygapophyseal joint. (Adapted from Barnsley L, Lord SM, Bogduk N, Teasell RW, Shapiro A. *The pathophysiology of whiplash*. In: Malanga, editor. *Cervical flexion-extension/whiplash injuries*. Spine: state of the art reviews. Philadelphia: Hanley & Belfus; 1998, p. 209-42.)

activation, multimodal interventions, simple reassurance, and encouragement to resume normal activities.⁶⁹

Treatment of chronic whiplash

Very few controlled studies of the treatment of chronic neck pain after whiplash injury have been conducted. The single most promising avenue has been percutaneous radiofrequency neurotomy, which was described previously.⁴⁷ This remains a palliative treatment, but one that is valuable for patients with constant and debilitating pain. Otherwise, the rather unsatisfactory options for the management of any chronic neck pain, as discussed earlier, can be applied.

CONCLUSION

Neck pain is a common disorder, but it is important to exclude serious underlying illness and neurologic involvement. Future progress in the field of chronic and refractory pain will depend on reliably identifying the source of pain, typically through invasive analgesic or provocation techniques, and testing potential treatments in methodologically sound studies in selected patients. Increasing sophistication of trials has enhanced the evidence base for some existing therapies, particularly activation for acute whiplash and exercise therapy for chronic neck pain.

Lumbar spine disorders

■ ZACHARIA ISAAC ■ JEFFREY N. KATZ

- Mechanical low back pain is the most common lumbar syndrome and a general category of pain that in severe refractory cases requires methodical evaluation.
- One of the most important roles of the physician is to recognize nonmechanical causes.
- Investigation is indicated for patients with persistent or progressive pain and those in whom a nonmechanical cause is suspected.

EPIDEMIOLOGY

Occurrence

Low back pain is the most frequent disorder of humanity after the common cold.^{1,2} Back pain develops in between 65% and 80% of the world's population at some point during their lives. More than 60 million adults in the United States report having back pain at some time in the past 3 months.³ The most prevalent impairments in people up to 65 years of age are musculoskeletal, with back and spine impairment being the most frequently reported subcategory at 51.7%.⁴ In the United States, mechanical low back pain is the fifth most common reason (2.8%) for physician office visits. Nonspecific low back pain accounts for 57% of these visits.⁵ Impairments of the back and spine are the chronic conditions that most frequently cause limitation of activity in people 45 years or younger, and they are the third most common reason for impairment in people aged 45 to 64 years.⁶

Impact

More than half of all patients with back pain improve after 1 week, and more than 90% are better at 8 weeks.⁷ The remaining 7% to 10% continue to experience symptoms for longer than 6 months. However, as many as 75% of individuals who improve are at risk of having a relapse of their back pain in the next 12 months.⁸ The high cost associated with low back pain is related to these individuals with chronic and recurrent pain. The cost of back pain in the United States is estimated to be higher than \$100 billion per year, the majority of which is indirect cost, including lost wages and lower productivity.⁹

Risk factors

Twin studies indicate that heredity plays a more important role than environmental factors do in disk degeneration, and it explains 74% of the variance in adult populations. Genetic influences have been confirmed by the identification of several genes associated with disk degeneration.¹⁰⁻¹²

Many of the environmental risk factors described for back pain involve occupational or psychological characteristics. Workers involved in heavy-duty labor who are older than 45 years have a 2.5 times greater risk for absence from work secondary to back pain than do workers 24 years or younger.¹³ Individuals with an initial episode of back pain lasting 3 months or longer have a 50% higher risk for recurrence in the following year than do those with an initial episode of only 1 day's duration.¹⁴

A number of psychological conditions are associated with back pain. Neurosis, hysteria, and conversion reaction are more frequently associated with acute back pain than depression is.¹⁵ Depression and anxiety are frequent complications of patients in whom chronic low back pain develops, and psychological distress predisposes to both a new episode and chronicity.

Although psychiatric comorbid conditions complicate treatment and can affect pain perception, true psychogenic pain is rare. Cigarette smoking is associated with increased risk for back pain, but the data are inconsistent.¹⁶ Although obesity is a minor factor in the causation of back pain, excessive weight is associated with longer episodes.¹⁷ Even though tobacco use, excessive weight, mood disturbances, and weakness of the core musculature have only weak associations with incident symptoms, they all represent modifiable factors.

CLINICAL EVALUATION

Introduction

Lumbar spine disorders can be categorized broadly as being mechanical, neuropathic, or medical in origin (Table 72.1). Up to 90% of patients with back pain have a mechanical or neuropathic reason for their pain.¹⁸ Mechanical implies that the pain is secondary to overuse of a normal anatomic structure, trauma, or deformity of an anatomic structure. Examples include discogenic pain, lumbar radiculopathy, spinal stenosis, facet syndrome, sacroiliac joint syndrome, and musculoskeletal sprain and strain. Neuropathic pain includes involvement of the peripheral or central nervous system either by direct compression of the spinal cord or spinal nerve roots or by changes in function of the neurologic system as a result of chronic pain. Given the difficulty of separating purely mechanical from purely neuropathic symptoms, many advocate the term *low back pain*. Patients with referred limb symptoms manifested as weakness, pain, sensory disturbances, or changes in reflexes caused by involvement of the spinal nerve are classified as having *radicular pain*. Defining a diagnosis is difficult because of the overlap of history, physical examination, and pain referral patterns of various pain generators and the high incidence of asymptomatic radiologic imaging findings.¹⁹ Frequently, however, no trauma or deformity can be identified with certainty in patients with low back pain. For the majority of patients with pain that responds to time, medications, and physical therapy, no specific diagnosis needs to be sought. Diagnostic functional testing with interventional spinal injection procedures is helpful in delineating the pain generator in refractory cases but requires thoughtful consideration of technical adequacy, placebo effect, and psychological pain behavior. Systemic illness accounts for the other 10% of adults with back pain.²⁰ More than 70 nonmechanical illnesses may be associated with back pain.²¹ Careful clinical evaluation helps distinguish patients with low back pain from those with systemic illness.

Evaluation of a patient with low back pain thus requires an organized approach that should be tailored to the specific complaints of the patient. Understanding the mechanism of pain generation helps determine what types of therapeutic exercise, activity modification, pharmacologic measures, spinal interventional procedures, and surgical options can be considered in the treatment algorithm.

History

The relevant medical history should be sought to evaluate for a possible underlying systemic illness.

A full occupational and social history is important to identify patients at risk for the development of low back pain. The association of work and the onset of pain is important in regard to compensation. The patient's opinion about the association of the pain and work must be determined, as well as the expectation of work-related sickness payments for injury and return to work.²²

TABLE 72.1**Categories of low back pain**

Category	Source/pathologic entity	Quality
Superficial somatic	Skin, subcutaneous tissue (cellulitis)	Sharp, burning
Deep somatic	Muscles, fascia, periosteum, ligaments, joints, vessels, dura (arthritis)	Sharp pain or dull ache, boring
Radicular	Spinal nerves (herniated disk, spinal stenosis)	Radiating, shooting, tingling
Neurogenic	Mixed motor sensory nerves (femoral neuropathy)	Burning
Visceral referred	Abdominal viscera, pelvic viscera, aorta (autonomic sensory nerves)	Boring, colicky, tearing
Psychogenic	Cerebral cortex (conversion reaction, malingering)	Variable

Site of pain

It is helpful to ask the patient whether the symptoms are predominantly axial or occur in the extremity (thigh, calf, or foot). The buttock region is often difficult to categorize because it can be affected by both axial low back pain and radicular pain secondary to irritation of the spinal nerve roots. Pain in the thighs or knees may be referred from elements of the spine, such as the intervertebral disks, zygapophyseal joints, sacroiliac joint, muscle, or ligaments, by somatic referral. Pain that radiates from the low back region to below the knees is usually radicular in origin and suggests a process affecting the spinal nerve roots.

Aggravating and relieving factors

Typically, disorders such as discogenic axial low back pain worsen with prolonged sitting, standing, and bending forward and improve with recumbency and changing position. Patients with disk herniations generally experience back and leg symptoms with sitting, driving, slouching, coughing, and sneezing. The symptoms are typically relieved by walking and shifting positions. Patients with spinal stenosis characteristically experience gluteal, thigh, and calf pain with standing, walking, and lumbar extension.

Some patients with medical disorders that affect the spine, such as osteoporotic compression fractures, traumatic fractures, pathologic fractures, or acute infection, may achieve pain relief with recumbency and even complete immobility, although some find no association with body position. Patients with spondyloarthritis classically report increased pain and stiffness when they remain in bed or seated for a few hours and relief with movement and exercise. Patients with spinal tumors often experience exacerbation with recumbency or nocturnally. Patients with viscerogenic pain may have symptoms that are worsened or exacerbated with meals or bowel movements, menstruation, or excess alcohol or nonsteroidal antiinflammatory drug (NSAID) consumption.

Physical examination**General examination**

When a medical or systemic cause of low back pain is suspected, a general physical examination should be completed in addition to examination of the spine. The objective of physical examination of the lumbosacral spine is to demonstrate static and dynamic abnormalities that can help sort out the disease entities that may be responsible for the low back pain.

Genital and rectal examinations should be performed in patients who have symptoms and signs suggestive of cauda equina syndrome or abdominal or pelvic pathology. These examinations may detect prostatic abnormalities, rectal cancer, or endometriosis. Low or absent rectal tone and absent voluntary anal contraction can be seen in patients with cauda equina syndrome. A number of ancillary physical examination tests may be used to confirm the abnormalities discovered during routine examination (Table 72.2).

Spinal examination

The spine is viewed for curvatures and postural deformities. A list is present if the first thoracic vertebra is not centered over the sacrum. Hyperlordosis or a flattened lumbosacral curve may be identified, and marked thoracic kyphosis is best noted from the lateral position. The spinous processes and sacrum can be palpated and percussed to determine whether any osseous injury is present. The ischial tuberosity and greater trochanter can be

TABLE 72.2**Ancillary tests for evaluation of low back pain**

Test	Tests for
Schober test	Lumbosacral motion
Contralateral straight leg-raising test	Nerve root compression
Bowstring sign	Nerve root compression (L5, S1)
Straight leg raise	Nerve root compression (L5, S1)
Femoral stretch test or hip extension	Nerve root compression (L2, L3, L4)
FABER test	Sacroiliac joint dysfunction, hip range of motion
Hoover test	Patient effort
Vertebral percussion	Osseous pain/fracture

FABER, flexion, abduction, external rotation.

**Cutaneous, motor, and reflex functions of the lower extremity.*

palpated for bursitis. The paraspinal muscles can be palpated for any areas of spasm, taut bands, or trigger points. In the supine position, leg lengths should be measured to document discrepancies.

Lumbar range of motion

The patient is asked to flex, extend, and laterally bend the lumbosacral spine. Patients with localized mechanical disorders maintain the lordosis while bending from the hips. Range of motion can be measured more precisely with an inclinometer.

Patients with spondyloarthritis may have an abnormal Schober test result. This test is performed by having the patient stand erect and marking the distance between the midpoint of the posterior superior iliac spines ("dimples of Venus") and 10 cm above that point. The patient is then asked to maximally flex forward while the more caudal spot is kept stationary. The more cephalad point on the tape measure should normally demonstrate at least 5 cm of excursion. This abnormality can also be seen with lumbar degenerative disk disease.

Classic teaching is that an increase in pain with forward flexion suggests an abnormality in the anterior elements of the spine, including the disk. This is probably mediated by increases in intradiscal pressure with forward flexion. Pain that is increased by extension suggests disease in the posterior elements of the spinal column, including the zygapophyseal joints.

Manual muscle testing

Of the possible neurologic abnormalities, persistent muscle weakness is the most reliable indicator of nerve compression.²³ It is useful to measure muscle strength on the Medical Research Council 6-point scale (muscle grade scores of 0 to 5). Examiner judgment is required to distinguish true weakness from pain-inhibited, apprehension-inhibited, or effort-dependent deficits in strength. At a minimum, the function of the three most commonly affected nerve roots should be tested (Table 72.3).

The L5 myotome includes the ankle dorsiflexors, great toe extensors, hip abductors, and ankle evertors. Asking the patient to heel-walk provides a

good screening test for the L5 nerve root. Severe weakness of the L5 myotome may be detected with the Trendelenburg test. The patient is asked to stand on one leg. Weakness of hip abduction is highlighted by sagging of the pelvis on the side opposite the affected leg. Patients may also have a Trendelenburg sign with hip osteoarthritis or synovitis, gluteal muscle tears, or a neurologic disorder.

The S1 myotome includes the gastrocnemius and hip extensors. Gluteus maximus strength is tested by having the patient lie prone and extend the hip against resistance with the knee bent. The gastrocnemius is not readily overcome with manual muscle testing even when weak, and a more sensitive screen for S1 weakness is completing more than 10 single-leg calf raises on each side.

The L4 myotome includes the quadriceps and ankle dorsiflexors. The L3 myotome includes the quadriceps but not the ankle dorsiflexors. Single-leg squatting is a good test to challenge the quadriceps muscle, which is often too strong to be overcome by the examiner's upper limb musculature.

The L1 and L2 myotomes include the hip flexors, which are tested by asking the supine patient to lift the thigh off the examining table. Having the hip externally rotated minimizes substitution of the rectus femoris of the quadriceps, which receives L2 through L4 contributions.

Neurologic examination

Upper motor neuron and peripheral nerve abnormalities may also cause neurologic dysfunction. Muscle spasticity, hyperreflexia, and the Babinski and Hoffman signs develop in patients with upper motor neuron dysfunction. Distinction among upper motor neuron, nerve root, and peripheral nerve lesions is essential for the differential diagnosis of back pain. Different disease processes preferentially affect the upper motor neuron (e.g., multiple sclerosis), nerve root (disk herniation), or peripheral nerve (diabetes).

Sensory examination

Sensory findings are less reliable than reflex or strength-testing findings. A given area of skin also receives innervation from two dermatomes, thus making sensory testing less specific for defining the affected nerve root. However, if a peripheral nerve is injured, a specific muscle may become paralyzed or specific skin areas may become anesthetic (Fig. 72.1). The L5 dermatome involves the buttock, lateral aspect of the thigh, lateral part of the calf, dorsal surface of the foot, and great toe. The S1 dermatome involves the buttock and the posterior thigh, posterior calf, and lateral foot areas. The L4 dermatome involves the anterior thigh region, anterior aspect of the knee, and pretibial region of the shin.

Deep tendon reflexes

Testing the deep tendon reflexes, especially the patellar reflex (L4) and Achilles reflex (S1), can be useful. However, no reliable reflex is available to test for L5. Older individuals may lose reflex function, particularly at the Achilles (which is likely to be symmetric), and previous episodes of nerve compression may have caused a loss of reflexes that may not return even with recovery of motor and sensory function.²⁴ Excessively brisk reflexes can be indicative of an upper motor neuron process such as cervical myelopathy.

Provocative maneuvers

The hip joints should be moved through their range of motion. Differentiation of hip pain from sacroiliac joint pain may be determined with the Patrick or "FABER" (flexion, abduction, external rotation) test. A Patrick maneuver producing low back pain suggests sacroiliac joint pain but can be nonspecific and is seen with spondylolisthesis, spinal stenosis, facet syndrome, and acute discogenic pain secondary to an annular tear. A Patrick maneuver producing groin or anterior thigh discomfort suggests hip disease. The greater trochanter can be palpated to determine the presence of bursitis. Sustained lumbar extension precipitating thigh or calf discomfort suggests lumbar stenosis.

Root tension signs

The straight leg-raising test detects irritation of the sciatic nerve (L5, S1). Passive raising of the leg with the knee extended stretches the sciatic nerve and its nerve roots and dural attachments. When the spinal nerve is inflamed and stretched, the patient will experience pain along its anatomic course. The pain associated with nerve root irritation is maximal between 20 and 70 degrees of elevation. Symptoms occurring at greater than 70 degrees of elevation may simply be related to mechanical pain secondary to muscle or ligamentous strain or joint disease.²⁵ Pain may also be experienced in the leg below the knee when the contralateral normal leg is raised, a finding known as the *crossed straight leg raise*. The crossed straight leg-raising test is insensitive but highly specific.²⁶

Fig. 72.1 Cutaneous sensory innervation. Anterior view of the lower extremities illustrating skin areas supplied by nerve roots (right) and peripheral nerves (left).

The neurologic examination is completed by testing for higher lumbar and sacral nerve root function. Dural irritation of nerve roots from L2 to L4 is tested by the femoral stretch test or reverse straight leg-raising test (Fig. 72.2). With the knee bent, the thigh is elevated from the examining table. The test is positive if pain is reproduced in the front of the thigh or the medial aspect of the leg.

Gait analysis

The patient's gait should be analyzed for heel and toe walking to screen for L5 and S1 myotomal deficits, respectively. Antalgia may be indicative of sacral, hip, knee, or foot and ankle injuries but can also be seen with acute radicular pain and with pain behavior. A forward stooped posture may be present in patients with spinal stenosis and in those with ankylosing spondylitis. A mechanical gait, which appears stiff and spastic, can be a component of cervical or thoracic myelopathy.

Reproducibility of physical signs

McCombe and colleagues²⁷ evaluated the reproducibility between three observers of 54 physical signs used for the evaluation of back pain. The signs that were adequately reproducible included measurements of lordosis and flexion range (Schober test), determination of the location of the pain with flexion and lateral bending, the straight leg-raising test, determination of the location of the pain in the thigh and legs, and sensory changes in the legs.

Nonorganic physical signs

Patients with psychological pain behavior often have subjective complaints that are much greater than their objective findings. Waddell and associates²⁸ described five tests that identify individuals with "functional" or

Fig. 72.2 In the femoral stretch test, the knee is flexed and lifted superiorly. Sharp pain generated in the anterior aspect of the thigh is considered to constitute a positive test.

“exaggerated” symptoms. A finding of three or more of the five signs is clinically significant. Patients who feign weakness during manual muscle testing may resist pressure for a few seconds and then release the muscle suddenly or in a manner resulting in a “cogwheel” or “give-way” effect. Because symptoms of psychological pain behavior do not exclude concomitant nociceptive pain and tissue injury, however, patients with psychological pain behavior warrant comprehensive treatment.

INVESTIGATIONS

Imaging

Plain radiographs

The Quebec Task Force on Spinal Disorders suggested that in patients without neurologic dysfunction, plain radiographs should not be obtained during the first week of an acute episode of back pain.²⁹ In adults younger than 50 years, the yield of unexpected important findings can be as low as 1 in 2500. By contrast, many individuals with radiographic abnormalities may be entirely asymptomatic.³⁰ Thus, congenital abnormalities, including spina bifida, transitional vertebrae, Schmorl nodes, and mild scoliosis, are only rarely causes of back pain.³¹ In normal persons older than 50 years, the prevalence of radiographic change is high: 67% have evidence of intervertebral disk degeneration, two thirds of whom are asymptomatic. In addition, osteoarthritis of the zygapophyseal joints noted on radiographs is not strongly correlated with symptoms.³²

When lumbar radiographs are obtained, a single lateral film offers the view with the highest yield in detecting vertebral compression fractures. Others have suggested that anteroposterior and lateral views are adequate for evaluation.³³ A coned lateral view of the lumbosacral junction and oblique views add little to the anteroposterior and lateral projections.³⁴ The anteroposterior and lateral views demonstrate the scoliotic curvature and sagittal balance, which can often help specialists in interpreting the biomechanics of the spine. Flexion and extension views can demonstrate segmental instability, a potential cause of unexplained back and radicular symptoms. Clinical practice guidelines have recommended that the criteria for obtaining plain films include older age, recent significant trauma, history of prolonged steroid use, previous cancer, recent infection, fever, intravenous drug abuse, unexplained weight loss, or pain with recumbency.³⁵ In a review of these guidelines, Suarez-Almazor and colleagues³⁶ reported that the recommendation for radiographs based on older age alone may result in excessive use of radiography during the initial visit. Use of the criteria of failure to respond to therapy and signs of systemic illness is more cost-effective. Patients with systemic illness and significant persistent symptoms often warrant imaging with magnetic resonance imaging (MRI) or computed tomography (CT), and negative plain radiographs do not provide sufficient reassurance of the absence of malignancy.

Radionuclide bone scintigraphy

Technetium-99m diphosphonate scans are useful in assessing for infection, tumors, inflammatory arthritis, and fractures.³⁷ The sensitivity of bone

Fig. 72.3 Technetium bone scan. Tracer activity throughout the axial skeleton is increased secondary to metastatic prostate cancer.

Fig. 72.4 Fracture. Computed tomography of the sacral spine demonstrates a sacral fracture not visualized with plain radiographs.

Fig. 72.5 Osteoid osteoma. Computed tomography of the thoracic spine demonstrates increased sclerosis associated with osteoid osteoma.

scanning is generally equal to that of MRI (90% vs. 96%), but it is less specific, for example, in detecting vertebral osteomyelitis (78% vs. 92%). Gallium and indium scans increase the specificity when used with a technetium scan but are less sensitive when used alone. Bone scintigraphy is better than MRI when evaluation of the whole skeleton is required, such as in patients with metastatic disease who may have unsuspected bone lesions in other parts of the skeleton (Fig. 72.3). The addition of single-photon emission computed tomography of bone can be useful for identifying facet pathology and predicting patients who will respond to intraarticular facet injection.³⁸

Computed tomography

CT is the best technique for assessing the bony architecture of the spinal column, including the sacroiliac joints, before changes are noted on plain radiographs.³⁹ In addition, the structural relationships of soft tissues (ligaments, nerve roots, fat, intervertebral disks) can be evaluated as they relate to their bony environment. CT is an excellent technique for identifying mechanical disorders, including spinal stenosis, spondylosis, spondylolysis, spondylolisthesis, trauma, congenital anomalies, and fractures (Fig. 72.4).⁴⁰ CT can visualize cortical bone destruction, calcified tumor matrix, and soft tissue extension of tumors affecting the spine and is superior to MRI in this regard (Fig. 72.5).⁴¹ CT can also be used in an outpatient setting to guide percutaneous needle biopsy of bony lesions.

Fig. 72.6 (a to c) Epidural hematoma. Postoperative sagittal and axial magnetic resonance imaging shows an epidural hematoma compressing the cauda equina.

The clinical significance of abnormalities noted on CT must be evaluated in the setting of the patient's clinical findings. In one study of asymptomatic subjects older than 40 years, 50% had abnormal findings, including disk herniation, spinal stenosis, and zygapophyseal joint degeneration.⁴² Thus, CT (as with MRI) should be used as a confirmatory test and not solely as a diagnostic test.

Magnetic resonance imaging

MRI has become the imaging modality of choice to evaluate lumbar spine disorders.⁴³ Patients who are not candidates for MRI evaluation include those on life support systems and those who have a cardiac pacemaker or ferromagnetic clips in the abdomen or brain or on blood vessels.

MRI is an excellent technique to view the spinal cord. It identifies syringomyelia, atrophy, cord infarction, cord injury, multiple sclerosis, intramedullary tumors, and hematoma (Fig. 72.6).⁴⁴ Use of contrast media (gadopentetate dimeglumine) for MRI improves the characterization of spinal cord tumors.⁴⁵ MRI delineates the extent of extradural tumor invasion of the spinal canal and compression or displacement of the spinal cord. It can identify the vertebral bodies in which bone marrow has been replaced with tumor (Fig. 72.7).⁴⁶ Use of gadolinium in patients with renal failure has been associated with a scleroderma-like disorder called nephrogenic systemic fibrosis (see Chapter 170).⁴⁷

MRI is an excellent technique for detecting infection of the spine, including diskitis, osteomyelitis, epidural abscess, paraspinal abscess, and myelitis.⁴⁸ It is more sensitive in detecting vertebral osteomyelitis than plain radiography or CT is.⁴⁹ Changes in the vertebral bodies and adjacent intervertebral disk spaces are visualized on T1-weighted images as areas of low signal intensity. On T2-weighted images, high signal intensity is seen crossing the involved bone and disk space.

MRI is also a useful technique for evaluating mechanical disorders of the lumbosacral spine. Intervertebral disk herniations can be identified in the sagittal plane and confirmed on axial images.⁵⁰ MRI is likewise useful in assessing traumatic and nontraumatic vertebral fractures. MRI can identify degenerative vertebral endplate changes and categorize them as edema, fatty, or sclerotic. MRI can reveal high-intensity zone lesions representing annular tears and neovascularization.

Fig. 72.7 Lumbar spine magnetic resonance imaging study of a patient with multiple myeloma and abnormal bone marrow signal throughout the vertebral bodies associated with remodeling and pathologic fractures.

Correlation between magnetic resonance imaging and clinical findings

As with CT and myelography, interpretation of the findings on MRI must take into account the clinical findings. Several separate studies have reported that in asymptomatic individuals, MRI identifies substantial abnormalities such as herniated disks (24% to 28% of the time), degenerative disk disease (>50%), and spinal stenosis (>5%).⁵¹

Comparison between magnetic resonance imaging and other modalities

In the diagnosis of herniated disks and spinal stenosis, MRI has a sensitivity equal to or greater than that of CT or myelography.⁵² In a study comparing MRI with contrast-enhanced CT for the diagnosis of a herniated disk confirmed at surgery, MRI had 90% accuracy, whereas CT had an accuracy rate of just 77%.⁵³ In addition, MRI was able to identify disk degeneration in 74 of 123 interspaces, whereas CT identified only 27. Currently, MRI is the technique of choice for investigation of spinal stenosis and disk degeneration. The major limitation of MRI is cost.

Other imaging techniques

A number of other radiographic techniques are available for evaluation of the lumbosacral spine. They are used infrequently in comparison to the techniques already discussed.

Spinal angiography permits identification of the arterial origins and the venous drainage of vascular lesions of the spinal cord and column.⁵⁴ Arteriovenous malformations are characterized by arteriovenous communication without an intervening capillary network.

Lumbar diskography is a procedure associated with the injection of contrast material through a percutaneous needle into the nucleus pulposus suspected of causing the back pain. Reproduction of the patient's pain is considered a positive test (Fig. 72.8). The test is used for patients with a degenerative disk who may be considered for spinal fusion, disk replacement, or intradiscal therapy because of persistent pain. Its clinical significance remains controversial.⁵⁵ MRI is equally sensitive in detecting disk degeneration by identifying high-intensity zones in an intervertebral disk (Fig. 72.9).⁵⁶ However, MRI is unable to reproduce the patient's symptoms. The role of diskography will be decided on the basis of its relevance to the patient's symptoms and the development of better nonsurgical therapies. Concerns are emerging about diskography potentially causing disk degeneration and herniations. A 10-year matched-cohort study by Carragee and coworkers⁵⁷ concluded that modern diskography techniques involving the use of a small-gauge needle and limited pressurization result in accelerated disk degeneration, disk herniation, loss of disk height and signal, and the development of reactive endplate changes when compared with match controls. Risk and benefit should be considered carefully when recommending procedures involving disk injection.

Fig. 72.8 Postdiskography computed tomography demonstrates painful grade 4 disruption of an annulus fibrosus.

Fig. 72.9 Disk degeneration. Magnetic resonance imaging demonstrates a high-intensity zone lesion in the L4/5 intervertebral disk.

CLINICAL LABORATORY TESTS

Patients with constitutional symptoms or who have failed conservative therapy may benefit from laboratory evaluation to exclude systemic processes such as infection, neoplasia, or visceral disease. The most useful tests in helping differentiate medical from mechanical low back pain is measurement of the erythrocyte sedimentation rate (ESR) or C-reactive protein level, which can suggest the presence of systemic inflammation.

Abnormalities in the complete blood count (hematocrit, leukocyte count, or platelet count) may be indicative of an inflammatory disorder, including neoplasms. Alterations in calcium concentration and alkaline phosphatase activity suggest diffuse bone disease (e.g., Paget disease, metastases). Elevated acid phosphatase activity may mirror the extent of metastases from prostatic cancer. Urinalysis can identify individuals with renal abnormalities (nephrolithiasis). Detection of occult blood in stool is a screening test for ulcers or gastrointestinal tumors.

ELECTRODIAGNOSTIC STUDIES

Electrodiagnostic studies can confirm the clinical suspicion of nerve root compression, define the distribution and severity of involvement, and document or exclude other disorders of nerves or muscles that can contribute to the patient's symptoms and signs. This tool is most helpful in cases in which peripheral entrapment, plexitis, anterior horn cell disease, or myopathy may be present. Electrodiagnostic tests can be helpful in identifying neurophysiologic abnormalities in patients in whom clinical examination (pain radiation, sensory changes, muscular weakness) does not necessarily indicate nerve root dysfunction.⁵⁸ Neurophysiologic tests can also document normal function in cases in which radiographic techniques have revealed anatomic abnormalities.

Electromyography

Electromyography (EMG) is the most sensitive tool for the diagnosis of radiculopathy.⁵⁹ EMG measures the action potentials of muscle fibers. As the nerve supplying a muscle becomes compressed, fibers to that muscle are lost and eventually replaced with regenerated fibers. This process of denervation and reinnervation occurs over time. EMG may not be able to document abnormalities until 3 to 4 weeks after the initial insult. A negative finding on EMG does not invalidate a patient's pain and sensory complaints but does make complaints of weakness and motor deficit much less likely to be based on spinal nerve injury.

Nerve conduction tests

In contrast to EMG, nerve conduction test results become abnormal as soon as nerve damage occurs.⁶⁰ Nerve conduction tests include evaluation of conduction velocity and amplitude along a segment of a peripheral nerve. They are helpful in distinguishing peripheral entrapment and neuropathy from radiculopathy. Changes on EMG may recede with resolution of the nerve impingement. However, patients in whom operative decompression provides relief of symptoms may have persistent abnormalities on EMG 1 year after surgery.⁶¹

NONMECHANICAL CAUSES OF LUMBAR SPINE PAIN

Most patients with low back pain have a mechanical cause of their symptoms and do not require any diagnostic tests (Table 72.4). However, a number of serious and potentially life-threatening disorders must be considered, including cauda equina compression, abdominal aneurysm, pancreatitis, infection, and neoplasm of various types. The first three are local disorders, but the latter often have systemic consequences. Clues to a potentially serious cause of back pain include the following:

- Constitutional symptoms: fever, weight loss, or increased pain on recumbency (e.g., sleeping in a chair) or nocturnally
- Acute, localized lumbosacral bone pain
- Visceral pain associated with alterations in gastrointestinal or genitourinary function

■ TABLE 72.4

BOX 72.1 INFECTIOUS DISORDERS AFFECTING THE LUMBOSACRAL SPINE*

Vertebral osteomyelitis

Bacterial

Tuberculous

Fungal

Spirochetal

Parasitic

Diskitis

Pyogenic sacroiliitis

*All these disorders may cause localized low back pain.

Cauda equina compression

Patients with cauda equina compression have a symptom complex that may include low back pain, bilateral sciatica, saddle anesthesia, or bladder and bowel incontinence. The most common causes of cauda equina compression include large central disk herniations, epidural abscess, hematoma, and tumor. MRI is the most sensitive diagnostic technique for detecting these lesions. Patients with cauda equina syndrome have the best opportunity for return of neurologic function if the cause of the compression can be eliminated within 48 hours.

Abdominal aortic aneurysm

An older patient with a history of vascular disease who is experiencing “tearing” or “throbbing” back pain with acute dizziness may have an expanding abdominal aneurysm. If patients complain of syncope or are hypotensive, they must be evaluated for an aneurysm on an emergency basis. Physical examination of the abdomen may reveal a pulsatile mass, abdominal bruits, and decreased pulsations in the lower extremities. Patients with expanding aneurysms may be evaluated with CT or ultrasonography, depending on the patient’s hemodynamic status. Those with an expanding aneurysm require surgical correction of the aneurysmal defect.

Infections

Patients with fever or weight loss (or both) may have an infection (or tumor) as a cause of their pain. The clinical findings in patients with a spinal infection depends on the infecting organism (Box 72.1). Bacterial infections cause acute, toxic symptoms, whereas tuberculosis and fungal infections are indolent. The pain associated with bacterial infections is persistent, present at rest, and exacerbated by motion. Physical findings include decreased range of motion, muscle spasm, and tenderness on percussion over the involved bone. Technetium bone scintigraphy or MRI can be used to investigate for the presence of local infection. MRI also detects soft tissue extension of lesions beyond the bony confines of the vertebral column. CT should be performed after MRI evaluation to delineate the bony architecture of lesions not visualized adequately with MRI (Fig. 72.10).

Definitive diagnosis of infection is based on recovery and identification of the causative organism from blood cultures or from aspirated material or

Fig. 72.10 Vertebral osteomyelitis. A computed tomography scan, axial view, demonstrates destruction of a vertebral body (V) with soft tissue extension (ST) into the paravertebral space.

biopsy samples of the lesion. Antibiotic therapy is adequate to cure most spinal infections. Surgical intervention for drainage is necessary if neurologic dysfunction has occurred or appears imminent secondary to the infection.

Vertebral osteomyelitis

Vertebral osteomyelitis follows hematogenous spread from an extraosseous source. Organisms may enter bone from nutrient arteries or from the venous plexus of Batson, a valveless system of veins that supplies the spinal column.⁶² Organisms that cause osteomyelitis include bacteria, mycobacteria, fungi, spirochetes, and parasites. The primary sources for spinal infections include the genitourinary tract, respiratory tract, and skin. The most frequently encountered organism causing infection is *Staphylococcus aureus* (in 60% of cases).⁶³ Gram-negative organisms may cause vertebral osteomyelitis in the elderly and in parenteral drug abusers (*Escherichia coli* and *Pseudomonas aeruginosa*,⁶⁴ respectively). In patients who have undergone surgery or suffered trauma to the spine, generally nonpathogenic organisms (diphtheroids, *Staphylococcus epidermidis*) may be associated with an indolent infection of the vertebral column.⁶⁵ Brucellosis may develop in workers in the meat-processing industry.⁶⁶ Tuberculous and fungal infections of the vertebral column occur most often in the elderly and other immunocompromised individuals. The clinical findings in a patient with tuberculous spondylitis are an insidious onset (potentially over a period of months to years) of pain over the involved vertebrae, low-grade fever, and weight loss (Fig. 72.11).⁶⁷

Disk infection

Spondylodiskitis occurs in the setting of concurrent extraspinal infection,⁶⁸ and in adults it is also associated with lumbar disk surgery. The ESR is almost universally elevated in the case of established disk space infections and often exceeds 100 mm/hr along with the presence of leukocytosis.⁶⁹ Plain radiographs may be normal at the onset of infection but will demonstrate increasing destruction with prolonged duration of infection

Fig. 72.11 Pott disease affecting the lumbosacral spine at L3 and resulting in rotatory scoliosis and lateral calcification.

Fig. 72.12 Infection of the intervertebral disk space. A plain lateral radiograph of the lumbar spine shows narrowing of the L5/S1 disk space with new bone formation at the L5 endplate (arrow) and a soft tissue mass pushing the great vessels anteriorly. This finding of narrowing of the disk space and new bone formation with displacement of the great vessels strongly suggests the diagnosis of spinal infection with a soft tissue abscess.

(Fig. 72.12). Radiographic evidence of established disk infection includes the following:

- Symmetric destruction of the adjacent endplate surfaces of two vertebrae
- Loss of disk height
- Reactive new bone formation
- Sclerosis of the bone endplates, with or without bone destruction or formation
- Soft tissue abscesses
- Kyphosis or subluxations after significant bone destruction has occurred

On CT, changes in the disk space and vertebral endplates can be seen, as can soft tissue abscesses (Fig. 72.13). The diagnosis is confirmed by identifying the causative organism from blood cultures, aspirated disk material, or biopsy specimens of infected adjacent bone. Six weeks of parenteral antibiotics and possibly additional oral antibiotic therapy usually provide adequate treatment for patients with radiologic evidence of disk space

Fig. 72.13 Spinal infection imaged by computed tomography of the lumbar spine. At the L5/S1 level, lucent areas in both psoas muscles and destructive changes in the intervertebral disk space suggest the presence of spinal infection with bilateral abscesses.

infection and a positive culture. The ESR provides a method of assessing the efficacy of therapy in these patients.

Surgical intervention, including drainage and débridement of spinal infections, is indicated in patients in whom paraparesis or paraplegia develops. The following factors appear to increase the risk for neurologic deficits:

- Older age
- Cervical or thoracic infection
- Infection with staphylococci as opposed to other organisms
- Coexisting diabetes or rheumatoid arthritis

When surgical treatment is selected, controversy exists concerning the use of bone grafts to achieve bone fusion. The experience of the spinal surgeon at the time of surgical débridement can help determine the appropriate course of action.

Pyogenic sacroiliitis

Pyogenic sacroiliitis is an unusual form of septic arthritis.⁷⁰ The disease is associated with acute symptoms, severe sacroiliac joint pain, and fever. This entity can be seen in postpartum women and also in injection drug users. Diagnosis of the causative organism may be achieved by blood cultures, fluoroscopically directed fine-needle aspiration, or open biopsy. Antibiotic therapy for 6 weeks is usually adequate to eradicate the infection without the need for surgical drainage.

Neoplasms

Tumors of the spinal column or spinal cord may cause pain at night or during recumbency. Both benign and malignant neoplasms can cause these symptoms. Nocturnal pain may be due to swelling of neoplastic tissues associated with inactivity in the supine position or to stretching of neural tissues over the neoplastic mass. A number of benign and malignant tumors are associated with involvement of the lumbosacral spine (Box 72.2). Benign lesions tend to cause local pain and involve the posterior elements of vertebrae. Malignant lesions cause more diffuse pain and systemic symptoms and more typically involve the anterior elements of vertebrae.

Patients with malignancies have pain that is gradual in onset but persistent and increasing in intensity. Physical examination shows localized tenderness over the lesion along with neurologic dysfunction if neural elements are compressed. Radiographic evaluation is useful in detecting the location and characteristics of the neoplastic lesion.

Osteoid osteoma

Osteoid osteoma is a benign tumor of bone. Approximately 7% of osteoid osteomas occur in the spine, most frequently in the lumbar area.⁷¹ The pain is aching and boring and frequently worse at night. The appearance of marked paravertebral muscle spasm and sudden onset of nonstructural scoliosis in a young adult requires an evaluation for this lesion, which typically occurs on the concave side of the scoliosis. The pain is often relieved by low-dose NSAID therapy. Hyperemia of the tumor may cause swelling and erythema of the skin if the lesion is superficial.

The radiographic finding of a lucent nidus with a diameter of 1.5 cm and a surrounding well-defined area of dense sclerotic bone is virtually pathognomonic of osteoid osteoma (Fig. 72.14). Bone scan or CT should be

performed if an osteoma is suspected and not found on plain radiographs (Fig. 72.15).^{72,73} Treatment of an osteoid osteoma is simple excision of the nidus and surrounding sclerotic bone.

Other primary spinal tumors

Neoplastic lesions may also occur inside the central spinal canal. These intraspinal neoplasms may be extradural, between bone and the outermost covering of the spinal cord (the dura); intradural-extramedullary, between the dura and the spinal cord; and intramedullary, in the spinal cord proper. Extradural tumors are most commonly metastatic in origin. Intradural-extramedullary tumors are primarily meningiomas, neurofibromas, or lipomas (Fig. 72.16). Intramedullary tumors are ependymomas or gliomas. MRI is useful in defining the location, size, and character of intraspinal lesions.

Multiple myeloma

Multiple myeloma is the most common primary malignancy of bone in adults and accounted for 27% of biopsied bone tumors in one series.⁷⁴ Patients typically range in age from 50 to 70 years. Low back pain is the initial complaint in 35% of patients. The pain is aching and intermittent at onset, aggravated by weight bearing, and improved with bed rest. Some patients may have radicular symptoms.⁷⁵ Significant neurologic dysfunction,

Fig. 72.15 Osteoid osteoma. Bone scintigraphy (posterior view) demonstrates increased uptake in T11. No other area of increased uptake in the skeleton is present.

Fig. 72.16 Neurofibroma. A transverse T1-weighted magnetic resonance image following intravenous gadolinium administration shows an enhancing mass occluding the right neural foramen of L2. Note how local bone erosion has widened the neural foramen.

including paraplegia, occurs more commonly with solitary plasmacytoma than with multiple myeloma.⁷⁶ Physical examination may demonstrate diffuse bone tenderness, fever, pallor, and purpura in the later stages of the illness. Spinal cord compression may occur with vertebral body collapse. Abnormal laboratory results may include anemia, leukocytosis, thrombocytopenia, elevated ESR, hypercalcemia, hyperuricemia, elevated creatinine, and a positive Coombs test. An increase in serum proteins is secondary to the presence of abnormal immunoglobulins in any of the five classes. Urinalysis may detect Bence Jones protein formed by the production of excess immunoglobulin light chains. Bone marrow aspiration or biopsy reveals an excess number of plasma cells of varied histologic grades.

Plain radiographs demonstrate osteolysis without reactive sclerosis and sparing of the posterior elements of the spine (Fig. 72.17).⁷⁷ Bone scintigraphy does not detect myeloma because of the absence of a reactive component of osteoblasts to the myeloma cells. MRI and CT are better techniques for identifying the presence and extent of myeloma lesions in bone and soft tissues. MRI is able to detect spinal bone marrow involvement in patients with asymptomatic myeloma. Myeloma is treated with chemotherapeutic agents to control growth of the malignant plasma cells. In patients with cord compression, decompression laminectomy is indicated, with or without local radiotherapy.⁷⁸

Skeletal metastases

Skeletal metastases are 25 times more common than primary tumors as the cause of neoplastic lesions in the spine. Autopsy results demonstrate that metastases to the thoracolumbar spine develop in 70% of patients with primary tumors.⁷⁹ Common primary sources of skeletal metastases include tumors of the breast, prostate, lung, kidney, thyroid, colon, uterine cervix, and bladder. Physical examination may demonstrate pain on palpation over the affected bone. Neurologic abnormalities are indicative of nerve root or spinal cord impingement. Laboratory findings may be abnormal depending on the underlying malignancy. Histologic features of biopsy specimens may suggest the identity of the primary tumor, but some lesions are too undifferentiated for identification.

Radiographic abnormalities depend on the character of the underlying malignancy. Kidney and thyroid metastases are typically osteolytic, whereas colon lesions are osteoblastic. Mixed lytic and blastic lesions are noted with breast, lung, prostate, or bladder tumors (Fig. 72.18). Plain radiographs may not show any abnormalities until 30% to 50% of bone calcium is lost.⁸⁰ Bone scans are positive in more than 85% of patients with metastases. MRI is able to show tumor in the spinal cord, extraosseous extension, and bone marrow replacement, whereas CT is more helpful in detecting cortical bone involvement and bone mineralization.⁸¹

Treatment of metastatic disease of the spine is directed toward palliation of pain. Radiotherapy is useful to control spinal pain. Decompressive laminectomy is recommended for patients in whom neurologic dysfunction has recently developed.

Rheumatologic causes

There are a number of rheumatologic causes of back pain that are discussed in detail elsewhere in this volume, including polymyalgia rheumatica (Chapter 156), fibromyalgia (Chapter 80), and ankylosing spondylitis (Chapter 115).

Primary bone disorders

Acute localized bone pain is usually caused by a fracture or expansion of bone (Box 72.3). The medical history, including a review of systems, may suggest the underlying cause of the patient's back pain (kidney stones with hyperparathyroidism, chronic cough with sarcoidosis). Physical examination often shows localized tenderness, typically with surrounding muscle spasm. Anemia or an increased ESR should raise suspicion for an inflammatory process. Serum chemistry may detect abnormalities in calcium metabolism associated with vitamin D deficiency (osteomalacia) or an

Fig. 72.18 Metastatic prostate cancer. A plain radiograph demonstrates osteoblastic lesions replacing the lower lumbar vertebral bodies and most of the bony pelvis.

elevated parathyroid hormone level (hyperparathyroidism). Elevations in alkaline phosphatase may suggest increased bone activity associated with neoplasms or Paget disease.

Plain radiographs may show osteopenia (Fig. 72.19) and areas of sclerosis related to healed fractures or Paget disease (Fig. 72.20). Microfractures cause significant pain and may not be detected with plain films. Bone scintigraphy is useful in this context for detection of the increased bone activity associated with fractures, and MRI can detect abnormalities of bone marrow that are associated with alterations in bone mineral density.

Therapy for patients with acute localized bone pain must be tailored to the specific disease process causing the illness. In those with severe bony compromise, stabilization of the spine may require bone grafting or rod placement (or both) (Fig. 72.21). Vertebroplasty can be used to treat vertebral compression fractures that remain painful and disabling after 6 weeks.⁸² In this procedure, methylmethacrylate is injected through a cannula into

the collapsed vertebral body. The cement stabilizes the fracture and may result in rapid relief of pain. In rare circumstances the cement will escape from the vertebral body. Kyphoplasty uses an inflatable bone tamp to reduce kyphotic fractures.⁸³ These procedures may also be associated with rapid relief of spinal pain in individuals with acute and subacute osteoporotic compression fractures. The efficacy of bone augmentation procedures is debated.

Herpetic neuralgia

Herpes zoster, also known as *shingles*, results from reactivation of latent varicella zoster infection within the dorsal root ganglia. It is characterized by a painful, unilateral vesicular eruption, usually in a dermatomal distribution. The thoracic and lumbar dermatomes are the most commonly involved sites of herpes zoster. Approximately 75% of patients have prodromal pain before the rash appears, which leaves a time frame during which the source of the acute back pain can be misconstrued as a sprain or strain. A common consequence of herpes zoster is postherpetic neuralgia.⁸⁴

Pain referred from other visceral organs

Disorders of the vascular, genitourinary, and gastrointestinal systems can cause stimulation of sensory nerves and the attendant perception of pain both in the damaged area and in superficial tissues supplied by the same segments of the spinal cord (Box 72.4). Colicky pain occurs in peristaltic waves and is associated with a hollow viscus, such as the ureter,

Fig. 72.22 Herniated intervertebral lumbar disk. A sagittal magnetic resonance image demonstrates extrusion of the L4-5 disk.

uterus, gallbladder, or colon. Throbbing pain is associated with vascular structures.

MECHANICAL CAUSES OF LOW BACK PAIN

Low back pain (also commonly called axial low back pain, mechanical low back pain, or nonspecific low back pain) can be defined as low back pain originating from but not limited to the facet joint, intervertebral disk, sacroiliac joint, muscles, and ligaments. This definition excludes malignancy; infectious, inflammatory, and rheumatologic causes; radiculopathy; and myelopathy. Patients may commonly have low back pain concomitantly with radiculopathic pain from spinal nerve root compression. Patients may also commonly have concurrent myofascial and centrally mediated neuropathic pain. Although the majority of patients with radicular symptoms improve with time, those with axial low back pain account for the largest group of patients with chronic persistent pain.

Spondylolysis and spondylolisthesis

Spondylolysis is a break in the pars interarticularis. If the defect permits displacement of one vertebra on another, it is termed spondylolisthesis (Fig. 72.22). Spondylolysis, with or without spondylolisthesis, is a common structural abnormality; however, only 5% of patients with the condition become symptomatic. Most patients with symptomatic spondylolisthesis complain of pain when their spine is placed in extension (increased displacement) as opposed to flexion (which tends to normalize vertebral body position). Nonoperative measures include patient education, flexion exercises, and a flexion back support. The development of progressive intervertebral disk degeneration at the listhetic level in the third decade of life typically coincides with the development of increasing back pain. These individuals may benefit from spinal fusion.⁸⁵

Intervertebral disk disorder

Mechanisms of pain

Degenerative disk disease can be associated with back pain by several mechanisms. The outer third of the lumbar disk anulus receives innervation from the sinuvertebral nerve or recurrent nerve of Lushcka.⁸⁶ Injury to the annular fibers, in the form of either an annular tear or herniation of the nucleus pulposus, can cause local inflammation and thus both chemical and mechanical sensitization of these annular fibers. Disk herniations can put tension on and sensitize the posterior longitudinal ligament and cause pain. Neural and vascular ingrowth into regions of the annular tear can create a chronic nociceptor. Because of noxious stimuli, the vertebral segment may attempt to splint itself, which can result in limited range of motion, regional areas of tenderness in the back, muscle spasm, taut bands, and trigger points. Spasms, taut bands, and trigger points can be painful in and of themselves but often stem from injury to deeper spinal structures.

Clinical features

Symptoms are often first seen in the 20- to 50-year-old age group. They are typically worse with prolonged sitting, standing, and forward bending and

Fig. 72.23 Herniated intervertebral disk. Axial magnetic resonance imaging demonstrates a large left paracentral disk extrusion.

are often relieved with walking and frequent positional shift. Symptoms can radiate to the limb without nerve compression via somatic referral. A herniated nucleus pulposus is associated with leg pain exacerbated by flexion of the lumbar spine or prolonged sitting. Individuals may experience sensory or motor deficits, or both. Bed rest does not accelerate recovery.⁸⁷

Investigations

If the pain persists and the patient wishes to consider more invasive therapy (e.g., injections or surgery), MRI or CT evaluation should be performed (Fig. 72.23; also see Fig. 72.22). MRI can demonstrate disk desiccation, focal protrusions, high-intensity zone lesions, and vertebral endplate changes. Degenerative disk disease can also be an asymptomatic finding that needs to be taken into account when interpreting the imaging results.

Treatment

For patients with disk herniation, persistent pain, and limitations in function, fluoroscopically guided epidural corticosteroid injections may be useful.⁸⁸ Corticosteroid is injected into the epidural space transforaminally, close to the location of the nerve root compression. Approximately 66% to 84% of patients will have benefit that is sustained even at 1-year follow-up.^{89,90} Maximal benefit is typically noted after 4 weeks. Leg symptoms usually respond better than axial symptoms do.

If injections are effective in alleviating the leg pain, the patient should be encouraged to increase physical activity, though with limitation of activities that increase intradiscal pressure, such as heavy lifting or sitting for long periods.

If conservative measures have not been effective, the patient may consider surgical intervention. The choice of surgical procedure (laminectomy with discectomy vs. microdiscectomy) is beyond the scope of this chapter. Some studies have shown that discectomy produces better pain relief than nonsurgical treatment does over a 4-year period, but outcomes of operative and nonoperative therapy are similar at 10-year follow-up.⁹¹ The Spine Patient Outcomes Research Trial (SPORT) demonstrated that surgery may offer more rapid relief of radicular symptoms and that the symptomatic benefit of surgery, as compared with nonoperative therapy, extends to 4 years. Of note, the intention-to-treat analyses in SPORT are not readily interpretable because of high rates of crossover from operative to nonoperative and from nonoperative to operative therapy. Thus, the conclusions of the study are based on the more interpretable “as-treated” analyses, which afford less protection against bias.^{92,93} Needless to say, the success of any of these surgical procedures is dependent on choosing patients who require surgery. Surgery for radicular symptoms is helpful in relieving leg pain, but it has not been shown to improve back pain.

Zygapophyseal (facet) joint syndrome

The zygapophyseal joint can also cause low back pain. Articular degeneration with zygapophyseal joint sclerosis may be associated with back pain.

Patients with facet joint syndrome can often experience back and buttock pain that is worse with standing and walking or lumbar extension and alleviated with forward flexion. Diagnosis of symptomatic facet syndrome requires anesthetization of the joint via an intraarticular block or anesthetization of the joint's innervation. At least two blocks are required to be confident that the facet joint is mediating the pain because of the high incidence of non-specific or placebo effects.⁸⁴

Lumbar spinal stenosis

Spinal stenosis can be defined as narrowing of the spinal canal secondary to degenerative changes that occur in the spinal canal with time (Figs. 72.24 and 72.25). Other forms of spinal stenosis occur secondary to congenital abnormalities and traumatic, postsurgical, or metabolic disorders. Patients

Fig. 72.24 Spinal stenosis. Magnetic resonance imaging, axial view, of the L3/4 disk level demonstrates osteophyte overgrowth, disk degeneration, and ligamentous hypertrophy. The cauda equina is compressed in the central area of the canal.

with spinal stenosis experience leg pain with standing or walking—the classic syndrome of neurogenic claudication.

The prevalence of narrowing of the lumbar spinal canal increases with age. Midsagittal narrowing to less than 10 mm is abnormal.⁹⁵ Myelographic, CT, and MRI studies have all shown that 20% to 25% of asymptomatic individuals older than 40 years have marked narrowing of the lumbar spinal canal. These *in vivo* measurements support the conclusion drawn from postmortem morphometry studies that many cases of “morphologic” lumbar spinal stenosis have no recognizable clinical expression.

Etiology and pathogenesis

The lumbar spinal canal is bounded anteriorly by the lumbar disks, vertebral bodies, and the posterior longitudinal ligament; laterally by the laminae and facet joints; and posteriorly by the ligamentum flavum (Fig. 72.26). The nerve root canals through which the spinal nerves exit the spinal canal are bounded anteriorly by the posterior surface of disks and vertebral bodies, posteriorly by facet joints and the pars interarticularis, and medially by the central vertebral canal.⁹⁶ Stenosis develops when relative narrowing of the dimensions of the lumbar spinal canal occurs. Many cases of lumbar spinal stenosis syndrome are the result of both congenital and acquired narrowing of the lumbar spinal canal, thus limiting the utility of any rigid etiologic classification.⁹⁷

Pathologic studies of the lumbar nerve root canal show that lumbar spondylosis is associated with a reduction in the vertical dimension because of disk space narrowing, posterior bulging of the intervertebral disks, retropulsion of remnants of the annulus fibrosus, and the formation of

Fig. 72.25 Lumbar spine stenosis. Computed tomography shows a thickened ligamentum flavum, facet joint hypertrophy, and posterior disk bulging. Note the absence of epidural fat along with a trefoil deformity of the lumbar spinal canal.

Fig. 72.26 (Left) The normal spinal canal. (Center) The spinal canal with central spinal and nerve root canal stenosis in the neutral position. (Right) The effect of lumbar extension on the spinal canal.

sclerotic ridges around the vertebral endplates. Osteoarthritic facet joints project osteophytes anteriorly from the superior articular processes, and synovial effusions, hemarthroses, and derangements of meniscal synovial folds are often present. Extension and rotation result in significant encroachment on the nerve root complex.⁹⁸ Flexion-extension myelography has shown consistent anterior displacement of the entire lumbar dural sac on extension as a result of shortening and thickening of the ligamentum flavum.⁹⁹

The precise mechanisms that produce neurogenic claudication are poorly understood. Neuropathologic assessment of patients has shown chronic segmental compression of nerves at regular intervals corresponding to the site of myelographic obstruction, together with confirmatory histologic features of nerve fiber damage. Abnormalities of the pial vessels have been reported,¹⁰⁰ and some patients have high cauda equina cerebrospinal fluid pressure.¹⁰¹ Any or all of these factors may play a role in the genesis of pseudoclaudication.

Clinical features

The most characteristic symptom is neurogenic claudication, defined as discomfort in the buttock, thigh, or leg on standing or walking that is relieved by rest and not produced by peripheral vascular insufficiency. Such discomfort is generally described as pain but is occasionally appreciated as numbness, weakness, or various combinations of these symptoms.

Neurogenic claudication is usually relieved by lying down, sitting, leaning forward on a shopping cart, or adopting a bent-forward position while walking (simian stance). The symptoms and signs typically affect multiple dermatomes. Some 40% of patients have bilateral symptoms. Restriction of straight leg raising (Lasègue sign) is present in only 10% of patients with lumbar spinal stenosis. Ankle jerks are absent in 40%, knee jerks are absent in 10%, and a small percentage have sensory loss or weakness.¹⁰² Anterior thigh numbness as seen in meralgia paresthetica can be produced by stenosis at the upper lumbar levels.¹⁰³

Bowel and bladder sphincter disturbances are relatively uncommon. Their presence constitutes an absolute indication for surgery to stabilize the deficit and allow some potential for recovery of bladder function.¹⁰⁴ Rarely, intermittent priapism has been reported as a manifestation of lumbar spinal stenosis.¹⁰⁵

A systematic review of the accuracy of clinical examination for the diagnosis of lumbar spinal stenosis that encompassed four studies and 741 patients found that having no pain when seated, improvement of symptoms when bending forward, the presence of bilateral buttock or leg pain, and neurogenic claudication were the most useful for diagnosing lumbar spinal stenosis. Additionally, having a wide-based gait and an abnormal Romberg test result also increased the likelihood of the clinical syndrome of lumbar spinal stenosis. Absence of neurogenic claudication decreased the likelihood of the diagnosis.¹⁰⁶

Investigations

The purpose of investigation is to confirm the diagnosis of lumbar stenosis syndrome and exclude other causes. Changes on plain films are insensitive for the diagnosis of spinal stenosis but provide information regarding alignment and general degenerative changes. Degenerative changes include narrowing of disk spaces, zygapophyseal joint osteoarthritis, and degenerative spondylolisthesis, commonly at L4/5.

CT can demonstrate articular facet hypertrophy, enlargement of laminae, hyperplasia, ossification of the ligamentum flavum, and disk prolapse. The technique allows definition of the osseous margins and the shape of the lumbar spinal canal. A trefoil shape of the lumbar canal is typical of severe lumbar spinal stenosis.

Contrast-enhanced myelography has largely been eclipsed by MRI and CT. Some physicians use contrast-enhanced myelography for surgical planning, however. Demonstration of obstruction to the flow of dye can be dependent on posture, with compression of the dural sac by the ligamentum flavum and disk being more severe in extension. The combination of contrast-enhanced myelography and CT directed at specific levels can demonstrate lateral recess or nerve root canal stenosis with greater definition than CT or myelography alone can.

MRI is the noninvasive study of choice. However, asymptomatic changes related to stenosis occur in 21% of subjects older than 60 years. MRI and contrast-enhanced CT are comparable in demonstrating spinal stenosis in any one segment.¹⁰⁷

Electrodiagnostic studies can also be helpful in the diagnosis of spinal stenosis. Of 37 patients with surgically proven lumbar spinal stenosis, 34 had an abnormality noted on EMG with evidence of one or more radiculopathies. Much of the usefulness of EMG lies in excluding peripheral neuropathy and peripheral nerve entrapment syndromes.¹⁰⁸

BOX 72.5 DIFFERENTIAL DIAGNOSIS OF LUMBAR SPINAL STENOSIS SYNDROME

Lumbar spondylosis without spinal stenosis
Herniated nucleus pulposus
Atherosclerotic occlusive peripheral vascular disease
Spinal tumors
Restless legs syndrome
Peripheral nerve entrapment
Cervical and thoracic spinal stenosis
Peripheral neuropathy
Anterior tibial compartment syndrome

Differential diagnosis

A number of conditions must be distinguished from lumbar spinal stenosis syndrome (Box 72.5). Peripheral vascular disease can be diagnosed on the basis of the history, physical examination, exercise, ankle brachial index, and vascular surgical consultation.¹⁰⁹ A herniated nucleus pulposus causing sciatica is associated with an abrupt onset. Patients with hip osteoarthritis have diminished range of motion and pain provoked by hip internal rotation. The possibility of two pain generators is common in this aging population. Trochanteric bursitis can cause regional thigh pain and can mimic radicular pain. Peripheral nerve entrapment may produce extremity pain. Lumbar spinal stenosis may be associated with stenosis in the cervical and thoracic areas, a combination that gives rise to complex manifestations. For example, myelopathy from more rostral narrowing of the spinal canal will result in difficulty walking and sphincter disturbance.¹¹⁰ Sacral fractures can entrap or irritate sacral nerve roots in the foramen and cause radicular pain referred to the buttock or thigh. Vascular disease can also be referred to the buttock and posterior part of the thigh. Hamstring injuries and ischial bursitis are soft tissue disorders that can refer symptoms to the posterior aspect of the thigh, whereas trochanteric bursitis and iliotibial band tightness can be associated with pain in the lateral aspect of the thigh.

MANAGEMENT OF LUMBAR SPINE DISORDERS

No single form of therapy is effective for all forms of back pain. Patients with systemic causes must be treated with specific therapies effective for their underlying disease as discussed earlier. The following section provides guidelines for the management of nonspecific back pain.

- Bed rest for more than 2 days is not helpful and may debilitate the patient. During the acute phase, patients are encouraged to ambulate as tolerated.
- Relief of pain may be accomplished most safely with nonprescription analgesics or nonsteroidal medication. Spinal manipulation may be helpful during the first 4 weeks in patients without radiculopathy.
- Low-stress aerobic activities can be started safely in the first 2 weeks of symptoms. Trunk muscle exercises should be delayed for at least 2 weeks.
- Patients should be encouraged to return to usual activities, both vocational and recreational, as soon as possible.

Frequently, the ability of patients to cope with their symptoms can be helped by careful explanation of the cause of the symptoms. The key to conservative management lies in the patient's acceptance of mild disability because most continue to be symptomatic in the longer term.

Conservative approaches

Components of a conservative management program for patients with low back pain include education, controlled physical activity, bed rest, exercise, and medication therapy in the form of NSAIDs and muscle relaxants. Bed rest should be kept to a minimum or eliminated. Scientific data support the recommendation to continue regular activity as tolerated rather than bed rest.¹¹¹

Physical modalities

Physical modalities may be used to diminish symptoms for short periods. Such forms of therapy include ice massage, hot packs, diathermy, ultrasound, and transcutaneous electrical nerve stimulation. These therapies may be applied by patients themselves or by a therapist. They are most useful as an adjunct to other treatments rather than as sole therapy.

Exercise

Physical therapy, particularly in the form of therapeutic exercises, may be particularly helpful in controlling mechanical low back pain.¹¹² As a generalization, patients with mechanical disorders of the disks prefer extension exercises, whereas those with stenosis prefer flexion exercises. In most circumstances, patients eventually perform a combination of both forms of exercise.

Patients may feel worse before they feel better following an exercise program. In one study of patients with chronic low back pain,¹¹³ 2 months was required before benefit was noted. The treating physician should find a physical therapist who is interested in taking care of patients with back pain and communicate concerns about patients to the therapist.

Exercises may also play a significant role in preventing back pain in asymptomatic individuals. In a comparison with educational strategies, mechanical support, and risk modification, exercises that strengthen the back and abdominal muscles were the only intervention associated with a decreased frequency and duration of low back pain.¹¹⁴

Oral drug therapy

The types of medication used for low back pain include analgesics, NSAIDs, muscle relaxants, and neuropathic pain medications. The potential toxicities must also be considered when choosing an agent for a patient.

Analgesics

Patients may benefit from acetaminophen. A slow-release form of the drug may allow a more prolonged analgesic effect in patients with back pain. The drug has a synergistic effect with NSAIDs and may be used in combination to increase analgesia without increasing toxicity.

Tramadol, a synthetic analgesic that binds opiate μ -receptors, is a useful agent that can be given independently or in combination with nonsteroidal drugs for the relief of chronic low back pain. This agent is most helpful for individuals who are unable to tolerate NSAIDs.

Narcotic analgesia should be reserved for patients with severe, functionally limiting pain and be used along with NSAIDs, other adjuvant analgesics, and a bowel regimen. Stronger narcotic analgesia should be reserved for patients who are unable to perform activities of daily living because of persistent pain. Continuation of narcotic analgesics in the outpatient setting should be discouraged unless the patient is committed to maximizing physical function through increased activity.¹¹⁵

Nonsteroidal antiinflammatory drugs

NSAIDs have analgesic properties in low doses and antiinflammatory properties at higher doses. The onset of action of the agents is important. With acute back pain, a rapid onset of action is important to control the symptoms quickly. With chronic pain, the onset of action is not as important as efficacy and safety over extended periods.

NSAIDs as a class of agents are effective therapy for low back pain.¹¹⁶ No specific selection criteria for the choice of a single agent have been established. Cyclooxygenase-2 (COX-2)-selective inhibitors are indicated for the treatment of low back pain in individuals with a history of peptic ulcer disease or gastrointestinal intolerance of dual COX-1/COX-2 inhibitors. Chronic use in the elderly is discouraged, and careful use of opiates may be safer.

Muscle relaxants

Muscle relaxants used for patients with low back pain work centrally to affect the activity of the muscle stretch reflexes. Drugs, including cyclobenzaprine, carisoprodol, and chlorzoxazone, have been shown to be more effective than placebo in treating patients with muscle spasm and, in combination with NSAIDs, augment the efficacy of the NSAID.¹¹⁷ The combination of an NSAID and a muscle relaxant offers significant relief of pain when compared with other combinations of therapies, including those with narcotics. The major side effects of muscle relaxants are drowsiness, headache, dizziness, and dry mouth.

Neuropathic pain agents

Tricyclic antidepressants have been shown in double-blind studies to relieve chronic pain. Low doses may be adequate to control symptoms.¹¹⁸ These drugs do not work immediately and may need to be continued for a number of weeks before decreased symptoms are noted. Selective serotonin reuptake inhibitors (sertraline, fluoxetine) are not as effective as tricyclics for relief of chronic pain.¹¹⁹ Mixed norepinephrine and serotonin reuptake inhibitors (venlafaxine and duloxetine) seem to have a more effective role in the management of chronic pain. Duloxetine has a Food and Drug Administration

indication for the treatment of chronic musculoskeletal pain and is often helpful for the treatment of chronic low back pain.

The second major class of neuropathic pain agents includes antiepileptic medications such as pregabalin, gabapentin, and carbamazepine. Neuropathic pain medications have a potential role when pain is mediated by both peripheral and central mechanisms. Chronic axial low back pain may also benefit from a trial of these agents. Strong evidence for the use of these agents is lacking, but judicious use can improve pain and quality of life and help restore sleep.

Injection therapy

Local or regional anesthesia given by injection is part of the therapeutic regimen for some patients with low back pain. The region injected may be an area of local trauma or a myofascial trigger point.¹²⁰ Trigger points are areas of the muscle that are painful at rest, prevent full lengthening of the muscle, weaken the muscle, refer pain in the muscle group on direct palpation, and cause a local contraction when palpated. A study by Garvey and colleagues¹²¹ suggested that needling the area with or without medication may have a beneficial effect. Injections may be given on a weekly basis for 3 to 4 additional weeks. It is controversial whether trigger point injections are beneficial.

Epidural injections

Epidural corticosteroid injections are used for patients with radicular pain who do not respond to less invasive management. The efficacy of these injections for the treatment of herniated disks and spinal stenosis with radiculopathy has been questioned, although they have been found to be effective in some patients.^{122,123} Benefits include decreased leg pain and more rapid return of sensory function. Epidural steroids may be administered via the interlaminar, transforaminal, and caudal routes. Fluoroscopic guidance improves the likelihood of delivering medication to the intended target, decreases the risk for vascular penetration, and enhances safety. Transforaminal epidural steroid injections place medication around the specifically involved nerve root and, in experienced hands, can offer effective treatment of radicular pain from a herniated disk.

Facet joint injection

Facet syndrome can mimic radicular pain. Diagnosis of facet syndrome is based on diagnostic anesthetization of the joint or its innervation. Corticosteroids can be injected to decrease pain.¹²⁴ These injections are done under fluoroscopic control to document appropriate placement of the needle. A facet joint receives innervation by the medial branches of the dorsal rami from the same level and the level above. If facet syndrome is confirmed on the basis of time-dependent medial branch anesthetic block, the medial branches can be denervated via radiofrequency ablation.^{125,126} The efficacy of facet injections and medial branch blocks has been questioned¹²⁷ and presents an area for further study.

Complementary therapies

Complementary therapies are used for a variety of medical problems, including low back pain. Therapies promoted for the treatment of low back pain include spinal manipulation, massage, acupuncture, and magnets.

Osteopathic physicians, chiropractors, and experienced physical therapists may offer manipulation as a therapy for low back pain. In a study of 215 patients who visited a physician and 242 who visited a chiropractor, overall satisfaction with care was three times greater with chiropractors than with physicians.¹²⁸ On the other hand, chiropractic care is associated with the greatest number of visits per episode and the highest outpatient cost when compared with other health care providers.¹²⁹

Therapeutic massage has benefit for individuals with chronic low back pain. Given once a week for a period of 10 weeks, this therapy has demonstrated benefit months after the last treatment. The efficacy of this form of treatment is limited to the availability of massage therapists.¹³⁰

Acupuncture is also commonly used for low back pain. A meta-analysis reported that for the primary outcome of short-term relief of chronic pain, acupuncture is significantly more effective than sham treatment and no additional treatment. Data are insufficient for drawing conclusions about acupuncture's short-term effectiveness relative to most other therapies.¹³¹

Another systematic review showed that for chronic low back pain, acupuncture is effective for relief of pain in the short term only. Acupuncture is not more effective than other conventional and "alternative" treatments. Data suggest that acupuncture and dry needling may be useful adjuncts to other therapies for chronic low back pain.¹³²

Surgical treatment

A small percentage of individuals with low back pain require surgical intervention to improve their condition. Indications for surgery vary according to the patient's characteristics but include sphincter and sexual dysfunction secondary to compression of the conus medullaris or cauda equina; severe radicular symptoms, particularly if progressive neurologic motor deficits are present; and radicular symptoms failing to respond to conservative management. Selection of the operative procedure is determined by the characteristics of the lesions and the skill of the surgeon with the specific technique.

With spinal stenosis, the success of surgical approaches depends on adequate decompression of areas of absolute stenosis and good judgment with respect to the adequacy of decompression of areas of relative stenosis. Surgery is most effective when patients have a clinical picture dominated by manifestations of nerve compression. The most common technical problem is inadequate neural decompression.¹³³ Comorbid conditions, including hip arthritis, osteoporosis, and cardiovascular disease, are associated with persistent pain after surgical correction.

Surgery for patients with radicular pain from a herniated disk primarily involves decompression; removal of the protruded, extruded, or sequestered disk material; and inspection and release of the tethered nerve root. Indications for concomitant spinal fusion remain controversial. Patients with spondylolisthesis, degenerative scoliosis, a history of previous surgery, segmental instability, or predominantly axial pain with concordant diskographic findings are possible candidates for concomitant fusion.

Patients with lumbar spondylolisthesis and symptoms of low back pain with or without neurologic symptoms from irritation of the spinal nerve roots may benefit from surgical fusion. In contrast, in patients with axial

low back pain and nonspecific degenerative changes, spinal fusion should be considered only after exhaustive attempts at nonoperative care and psychological counseling. In this small subpopulation, spinal fusion may be considered for patients with two or fewer adjacent degenerated disks demonstrated to be concordant for reproducing the patient's symptoms on non-sedated lumbar diskography with at least one asymptomatic level. Even in this highly selected population, concerns about adjacent-level degeneration and subsequent return of pain can occur. Prosthetic disks hold some promise in terms of reducing adjacent-level degeneration; their efficacy has been reported to be comparable to that of fusion.¹³⁴

The SPORT studies have shed additional light on the role of surgery in patients with back pain. The SPORT investigators performed three parallel studies involving patients with herniated nucleus pulposus and sciatica, patients with lumbar spinal stenosis and neurogenic claudication, and patients with degenerative spondylolisthesis and stenosis with neurogenic claudication. Each trial was compromised by high rates of crossover from one randomized group to the other. Essentially, about half of the SPORT subjects did not receive the intervention to which they were randomly assigned. Consequently, the investigators presented sophisticated as-treated analyses that took advantage of the unique SPORT data. These analyses consistently show that in the first 4 years of follow-up, outcomes are better following surgery than following nonoperative therapy. Longer follow-up will determine whether these differences persist.^{135,136}

Unfortunately, despite adequate conservative and operative management, some patients are left with ongoing severe back pain and limitation. Multidisciplinary pain management and functional restoration techniques should be considered for these patients, and management involves both physical and psychological assessment and treatment.¹³⁷

The shoulder

■ SEAMUS E. DALTON

- Shoulder motion involves four articulations: the glenohumeral, acromioclavicular, sternoclavicular, and scapulothoracic.
- Stability of the shoulder is dependent on static and dynamic restraints.
- Common shoulder disorders include rotator cuff tendinopathy, capsulitis (frozen shoulder), glenohumeral arthritis, and acromioclavicular syndromes.
- Most shoulder conditions can be diagnosed clinically with a careful history and physical examination.
- Patients with tendinopathy have pain during active and resisted motion, but passive range of motion tends to be normal. Degenerative tendinopathy is common, age related, and often asymptomatic.
- In capsulitis and glenohumeral arthritis, active and passive motion is painful, there is no pain on resisted motion, and passive motion is decreased.

FUNCTIONAL ANATOMY

The clavicle, scapula, and humerus make up the bony skeleton of the shoulder girdle. Its relationship with the axial skeleton is maintained through muscular attachments and the articulation of the clavicle with the thoracic cage at the sternoclavicular joint. Shoulder movement occurs through motion at four articulations: the glenohumeral, acromioclavicular, sternoclavicular, and scapulothoracic. The scapula acts a mobile platform on which glenohumeral motion can take place. The glenohumeral joint is a multiaxial joint that allows the greatest freedom of movement of any joint in the body, though at the expense of stability. Ligamentous support is important in maintaining static stability of the joints of the shoulder and allowing synchronous movements to take place. Some constraint is also afforded to the head of the humerus through the subacromial joint by the overlying acromion and coracoacromial ligament. Muscles act as prime movers at the shoulder, as well as provide dynamic stability to the glenohumeral joint. The shoulder girdle also acts as a conduit for the brachial plexus and major vessels supplying the upper limb.

Glenohumeral joint

The glenohumeral joint allows a certain amount of translation, which increases when the musculoligamentous support is lax. Inherent bony stability is poor because of the shallow glenoid fossa and larger humeral head but is enhanced through a process of joint adhesion and negative intra-articular pressure. The glenoid labrum is a rim of fibrocartilage at the periphery of the glenoid that effectively deepens the glenoid fossa, thereby increasing its diameter and contact with the humeral head and affording some increased stability.

The joint capsule is thin and lax, especially inferiorly, which allows rotation and elevation, but becomes taut at the extremes of motion, with tensile load in one region of the capsule being associated with laxity in the contralateral region. In conditions in which the capsule contracts, glenohumeral motion is restricted. Restriction in the capsule posteriorly results in increased superior and anterior translation with forward flexion, which can lead to subacromial impingement and is also implicated in other clinical conditions of the shoulder.

Glenohumeral ligaments

The joint capsule thickens anteriorly to form separate components known as the glenohumeral ligaments, which act to strengthen the anterior and inferior capsule. The superior glenohumeral ligament (SGHL) runs from the anterosuperior aspect of the glenoid to the proximal edge of the lesser tuberosity of the humerus, with the middle glenohumeral ligament (MGHL) running just below this. The inferior glenohumeral ligament (IGHL) runs from the anteromedial aspect of the glenoid to the distal edge of the lesser tuberosity and proximal shaft of the humerus and has three components enabling it to sustain loading in multiple directions (Fig. 73.1). It is important in providing anteroinferior stability to the joint, particularly with the arm in abduction and external rotation, and is the major restraint of external rotation in the neutral and abducted position.¹ It has also been shown to provide some posterior stability, especially in flexion and internal rotation. The joint capsule functions like a hammock or cylinder, with many regions acting as a restraint to external rotation.

Anatomic variants in glenohumeral ligaments

Deficiencies in the glenohumeral ligament complex are important in the development of instability. Several studies have described a number of anatomic variations in the glenohumeral ligaments and capsulolabral attachments that need to be differentiated from truly pathologic conditions. With the advent of magnetic resonance imaging (MRI) and arthroscopy, these variants have been demonstrated in both the normal and symptomatic population (Fig. 73.2). An example is the variable development of the MGHL and anterosuperior labrum, with normal variants such as the Buford complex (absent anterior superior labrum and cordlike MGHL) and sublabral hole (or window) often mistakenly being identified as a pathologic lesion (e.g., a Bankart defect, or an isolated tear in the anterior inferior glenoid labrum).

Coracohumeral and coracoacromial ligaments

The coracohumeral ligament originates from the coracoid process with variable insertion into the rotator interval or anterior rotator cuff, and in conjunction with the SGHL it limits inferior translation and external rotation of the adducted shoulder. The coracoacromial ligament extends from the undersurface of the medial acromion to the superolateral border of the coracoid process, although several types have been described.² It acts as a tension band supporting the acromion and coracoid and has an important role in transmitting force from the surrounding muscles. Along with the acromion, it acts as a roof over the subacromial space under which the rotator cuff tendons slide, with the subacromial bursa lying between. This structure has been implicated in the pathology of impingement of the shoulder. The transverse humeral ligament runs between the greater and lesser tuberosities and covers the long head of the biceps tendon (Fig. 73.3).

Stabilizers of the shoulder

Stabilizers of the shoulder can be divided into two groups: static and dynamic (i.e., passive and active restraints). The capsule, labrum, glenohumeral ligament, and to a lesser extent, the coracohumeral ligament can be thought of as static stabilizers of the glenohumeral joint. There are two sleeves of muscles about the shoulder: superficial and deep. The outer sleeve of muscles comprises the deltoid, teres major, pectoralis major, latissimus dorsi, and trapezius muscles. They act as prime movers of the humerus, although the trapezius acts through movement of the scapula and clavicle. The deltoid muscle has three bellies—anterior, middle, and posterior—that respectively produce flexion, abduction, and extension of the shoulder. All three muscles converge to an insertion on the deltoid tubercle on the lateral aspect of the humeral shaft. The combination of these large muscles (which

provide abduction, flexion, extension, adduction, and a degree of rotation) with the deep layer of rotator cuff muscles (which provide more rotation of the humeral head and act as a stabilizing force) allows expansive movement of the arm for actions such as reaching behind one's back or behind the head. However, in certain positions, overactivity of these muscles,

notably the deltoid and pectoralis major, may actually reduce glenohumeral stability.³

The deep group comprises the rotator cuff muscles (supraspinatus, subscapularis, infraspinatus, and teres minor) and the tendon of the long head of the biceps. This layer acts dynamically to stabilize the humeral head in the glenoid fossa during shoulder movement while simultaneously providing rotation (through the subscapularis, teres minor, and infraspinatus) and abduction (through the supraspinatus).

Rotator cuff

The rotator cuff muscles originate from the scapula and attach to the greater (supraspinatus, infraspinatus, and teres minor) and lesser (subscapularis) tuberosities of the humerus. The rotator cuff has also been shown to provide some passive restraint to glenohumeral joint translation, especially posteriorly. During the initiation of shoulder abduction or elevation, the larger, more powerful deltoid muscle, if unopposed, would pull the humeral head superiorly toward the acromion. The rotator cuff muscles and the biceps tendon act as humeral head depressors to prevent such translational movement superiorly. This is known as the "force couple." The subscapularis also acts to resist the tendency of the humeral head to sublux anteriorly in the upper ranges of abduction, although its role is less important than previously thought and it has been found to be less effective at the extremes of motion.⁴ Dysfunction of the rotator cuff muscles, through either weakness or a tear, results in diminished stabilization of the humeral head, which leads to weakness of the arm in elevation, as well as superior migration of the humeral head, thereby increasing the likelihood of subacromial compression or impingement. Therefore, the four tendons of the rotator cuff grip the humeral head and act as guy ropes to stabilize it during shoulder movement and resist this sliding tendency within the joint.

A gap or thinning of the cuff is present between the supraspinatus and subscapularis tendons and is known as the "rotator interval," which is composed of the coracohumeral ligament, the SGHL, and part of the joint capsule. The rotator interval is of variable size, has a role in the prevention of inferior translation of the humeral head, and may be implicated in some patients with anterior glenohumeral instability. Two functionally different parts of the rotator cuff have been identified, and it has been reported that the coracohumeral ligament is an important structure in the rotator interval and, in conjunction with the SGHL, has a role in control of external rotation, as well as inferior translation, in the adducted shoulder.¹

Biceps tendon

The biceps tendon arises from the superior labrum or directly from the supraglenoid tubercle, although a number of variations in this attachment have been reported. The long head of the biceps has been described as a humeral head depressor in full abduction and has also been shown to contribute to anterior stability of the shoulder. It has been reported to be a significant dynamic restraint in the abducted shoulder near the end range of rotation. However, one study suggested that its role as a stabilizer of the

Fig. 73.3 Ligamentous and musculotendinous attachments about the shoulder joint.

glenohumeral joint is either a passive one or dependent on the tension associated with elbow and forearm activity.⁹

Nerve supply

The nerve supply to the glenohumeral joint is provided by the peripheral nerves supplying muscles acting on the joint: the axillary, suprascapular, subscapular, and musculocutaneous nerves. Innervation is via the fifth, sixth, and seventh cervical roots, and the brachial plexus passes anterior and inferior to the glenohumeral joint.

Other joints

Acromioclavicular joint

A fibrous disk separates the noncongruent surfaces of the distal end of the clavicle and the acromion and allows movement at this joint. During abduction and elevation the clavicle rotates through 30 to 40 degrees, and this rotation occurs largely at the sternoclavicular joint. There is a small amount of movement at the acromioclavicular joint, and compressive force is applied to the joint in full elevation and horizontal adduction, which is the basis of clinical stress tests applied to this joint. The joint is stabilized posteriorly by the posterior transverse ligament and inferiorly by the inferior ligament, and the deltoid and trapezius muscles provide some anterior and superior stability through their fascial layer. Of particular importance are the conoid and trapezoid (coracoclavicular) ligaments, which maintain the close relationship between the scapula and clavicle during shoulder movement.

Scapulothoracic joint

The scapula lies against the posterolateral aspect of the thoracic wall and rotates and slides laterally in abduction, elevation, and flexion. It provides the origin for the rotator cuff muscles, as well as the deltoid muscle, and the trapezius inserts along its superior aspect. The scapulothoracic joint represents the articulation between the scapula and the thoracic cage, and motion here is important for normal functioning of the shoulder.

Elevation and abduction of the arm involve synchronous motion at the glenohumeral and scapulothoracic joints. As elevation increases above 90 degrees, so does the proportion of scapulothoracic motion relative to

glenohumeral motion. Scapulohumeral rhythm is representative of the ratio between movement at these two joints and is important in several shoulder disorders. Disturbance of the normal scapulohumeral rhythm affects the biomechanics of the shoulder joint and may result in secondary impingement. This is seen in swimmers or participants in overhead sports, in whom muscle imbalances such as serratus anterior fatigue can lead to tendinopathy or impingement in this manner. Several muscles (levator scapulae, serratus anterior, trapezius, rhomboids) act to stabilize and move the scapula, and the balance between scapula elevators, rotators, depressors, retractors, and protractors determines scapulothoracic motion. Scapular control by these muscles is an important factor in glenohumeral instability and rotator cuff dysfunction. Muscle imbalance about the scapula can also lead to fatigue and overactivity of the levator and upper trapezius muscles particularly.

Sternoclavicular joint

Like the acromioclavicular joint, the sternoclavicular joint contains an intraarticular fibrous disk that allows rotation of the clavicle during abduction and elevation. Strong ligaments stabilize this joint anteriorly and posteriorly.

Bursae

The number and extent of bursae around the shoulder are variable. The subacromial bursa lies between the rotator cuff and overlying acromion but does not consist of a distinct sac, and its synovial layers blend in with and are firmly attached to the acromion and rotator cuff. In subacromial impingement there is reactive inflammation of this bursa, and the increased expression of cytokines in the synovium has been implicated in the pathogenesis of tendon degeneration. The subscapularis bursa communicates with the synovial joint cavity between the SGHL and MGHL, and the synovial membrane of the joint invests the tendon of the long head of the biceps. Other bursae include the subdeltoid, coracoid, infraserratus, and bursae at the insertion of the tendon of the trapezius and at the tendon insertions on the humerus.

HISTORY AND PHYSICAL EXAMINATION

History

Shoulder pain is seen in association with several medical conditions and may be referred from cervical, thoracic, or abdominal sources. Any history suggestive of such a secondary cause, such as diabetes or the Raynaud phenomenon, may be crucial in making the diagnosis. Similarly, the mechanism of any precipitating injury is of value. A fall on an outstretched arm can give rise to instability in a younger patient or a rotator cuff tear in the elderly. A fall on the point of the shoulder may result in injury to the rotator cuff or acromioclavicular joint. Throwing injuries tend to stress the capsulolabral complex and ligament attachments of the glenohumeral joint and can also give rise to rotator cuff or bicipital tendinitis.

A thorough history is essential because the location and type of pain vary between conditions. Pain referred from the cervical spine is often maximal over the suprascapular region, with associated paresthesia or pain referred to the upper limb. Although acromioclavicular and sternoclavicular pain is usually localized to the involved joint, it often radiates proximally, even into the neck. Pain from rotator cuff pathology is usually felt at the outer aspect of the upper part of the arm or the deltoid region. Adhesive capsulitis tends to give rise to an intense aching deep in the shoulder, although features similar to rotator cuff pathology are common in the early stages. Pain radiating into the arm may indicate cervical pathology, thoracic outlet syndrome, compressive neuropathy, brachial neuritis, or a neuropathic pain syndrome (e.g., complex regional pain syndrome). Night pain tends to be either sharp pain associated with movement, indicative of rotator cuff tendinopathy or acromioclavicular pathology, or a deep, constant ache more suggestive of capsulitis or a chronic tear of the rotator cuff.

Frequently, the severity and chronicity of a patient's pain do not correlate with the underlying pathology and presumed source of nociception. A process of central sensitization offers the best explanation for this, and early identification of neuropathic pain has important implications for the management of patients with chronic shoulder pain.

Examination

Inspection

Inspection should be carried out from the anterior, posterior, and lateral aspects. Difficulty undressing may indicate functional limitations. Areas of

erythema and bruising should be noted. Though uncommon, swelling of the shoulder joint may be seen anteriorly in the projection of the subscapularis bursa. Deformity of the shoulder girdle occurs with separation of the acromioclavicular joint or fracture of the clavicle or humerus. It is important to look for positioning of the shoulder such as asymmetric elevation or overprotraction. Neck position should also be recorded. Rupture of the long head of the biceps tendon is readily seen with anterior bulging in the upper part of the arm. Muscle wasting may be present in patients with cervical or brachial neuropathy (e.g., suprascapular nerve entrapment) but is also seen in the supraspinatus and infraspinatus muscle bellies with chronic rotator cuff tears. Scapulohumeral and scapulothoracic rhythm during elevation should be assessed and any asymmetry noted. A number of types of scapular dyskinesis have been described.⁶ Winging of the scapula, demonstrated by asking the patient to do a push-up against the wall, is indicative of serratus anterior weakness (as in long thoracic nerve palsy) but can also occur with muscular dysfunction. Excessive depression of the scapula (“dumping”) that is maintained through a range of abduction of the shoulder often indicates weakness of the upper trapezius or overactivity of the pectorals and latissimus and can lead to pain and symptoms of subacromial impingement or brachialgia and thoracic outlet syndrome.

Palpation

Palpation should be performed to identify tenderness, swelling, and instability of the acromioclavicular, sternoclavicular, and glenohumeral joints. Tenderness over the tendon of the long head of the biceps at the bicipital groove is common with bicipital tendinitis but may also occur with subscapularis tendinopathy, and comparison with the opposite shoulder is necessary because this region is often sensitive to touch. There may be tenderness over the rotator cuff insertions to the greater and lesser tuberosities, but this is not always present in rotator cuff tendinopathy. Acute calcific tendinitis results in exquisite tenderness over the involved tendon. The lateral margin of the subacromial joint can be palpated for swelling and tenderness, and the glenohumeral joint itself may be tender with acute instability or capsulitis. An effusion of the glenohumeral joint should be differentiated from subacromial swelling, although there may be communication between the two when a full-thickness tear of the rotator cuff is present. Osteophytes may be palpable at the margins of these joints, as well as crepitus, particularly with glenohumeral osteoarthritis.

Instability of the acromioclavicular and sternoclavicular joints is readily demonstrable, but glenohumeral instability requires a more detailed examination that combines assessment of laxity in the anterior, posterior, and inferior directions with stress and apprehension tests to determine the presence of symptomatic instability. Such assessment must be carried out in young adults with shoulder pain because underlying instability is a frequent cause of tendinitis around the shoulder. Muscles of the shoulder girdle and neck region should be palpated for trigger points and tender points, which are typically present with myofascial syndromes and fibromyalgia, respectively. Scapulothoracic crepitus is common and frequently found in association with muscular complaints and probably represents a frictional sound as the scapula glides across the underlying muscle layers. Rarely, it may reflect changes in the bony structure of the deep surface of the scapula or underlying ribs, such as an osteochondroma of the scapula or a rib exostosis, although these lesions tend to give rise to a more pronounced snapping sound and may result in deviation of the scapula away from the chest wall.

Range of movement

Active and passive range of motion should be assessed in the planes of abduction, forward flexion, and external rotation, both with the arm by the side and at 90 degrees of abduction. Internal rotation is frequently assessed as a combined maneuver with extension by bringing the hand up behind the back. Such movement is limited in many periarticular conditions, and true assessment of glenohumeral joint restriction is best done by measuring internal rotation with the arm by the side and the elbow extended. Internal rotation should also be assessed with the arm in abduction. Any limitation of movement should be noted, as well as any discrepancy between active and passive motion. Glenohumeral joint pathology is unlikely in the presence of a normal range of passive motion.

Further assessment should include passive adduction of the flexed and internally rotated shoulder to look for tightness of the posterior capsule and external rotators because such tightness is often seen in chronic conditions. Resisted shoulder movements are performed to assess the involvement of muscles and tendons. The patient is asked to resist a specific movement to elicit an isolated, isometric contraction in a particular muscle group. The supraspinatus is tested with the arm abducted to 90 degrees, flexed to 30 degrees, and internally rotated (i.e., thumb downward). The examiner then resists abduction from this position (“empty can” sign). However, in

symptomatic cases this test is frequently very painful, and resisted flexion (at 30 degrees of flexion) with the arm internally rotated is often a sensitive and less aggravating test of rotator cuff (particularly supraspinatus) function. Resisted internal rotation tests the subscapularis (best done with the hand behind the back or placed across the abdomen, known as the lift-off and belly press tests, respectively), and resisted external rotation tests the infraspinatus and teres minor (although 22% to 33% of the external rotation force can be attributed to the supraspinatus⁷). Resisted abduction should also be carried out with the arm by the side. Biceps function can also be tested by resisting shoulder flexion with the elbow extended (Speed test) or by resisting supination with the elbow flexed to 90 degrees (Yergason test), although the sensitivity and specificity of these tests are questionable. Any assessment must include an examination of the cervical spine to assess range of motion and the presence of any referred upper limb pain (see Chapter 71).

Special movements

Specific examination techniques are used to further localize the source of pain.⁸ Various tests for impingement have been described. In one, the arm is flexed to 90 degrees, adducted, and then forcefully internally rotated and slightly elevated by the examiner while the scapula is stabilized by the examiner's other hand (Fig. 73.4a). In another variation the arm is placed in the adducted, flexed, internally rotated position and the patient is asked to externally rotate the arm against resistance (see Fig. 73.4b). A further impingement test is carried out by passively forcing the arm into full forward flexion while the examiner stabilizes the top of the scapula with the other hand (see Fig. 73.4c). In all situations a positive test is recorded if pain is felt as the subacromial bursa and the rotator cuff are forced against the undersurface of the acromion, although it appears likely that these tests also provoke contact between anatomic structures associated with internal impingement.

A number of clinical tests for labral and biceps pathology have been described, but their diagnostic validity remains uncertain. The O'Brien test

Fig. 73.4 Impingement tests. (a) Forced passive internal rotation. (b) Resisted external rotation. (c) Forced passive full forward flexion.

Fig. 73.5 Adduction stress test of the acromioclavicular joint.

Fig. 73.6 The anterior draw test.

has been described as a provocation test for superior labral and biceps anchor pathology (superior labrum anterior to posterior [SLAP] lesions), but it also elicits pain in those with acromioclavicular joint disorders.

Pain at the acromioclavicular joint can be localized by performing various stress tests. In one, the arm is held with the elbow and shoulder extended and then passively adducted across behind the back (Fig. 73.5). In another less specific maneuver the arm is abducted to 90 degrees and then adducted across the patient's chest under the chin. In both tests pain is felt over an inflamed acromioclavicular joint at the limits of these movements. Assessment for thoracic outlet syndrome is difficult, and several maneuvers have been described that may provoke symptoms of neurovascular compression (see Chapter 81). A number of upper limb neural tension tests have also been described and are useful when assessing the etiology of diffuse or nonspecific upper limb pain.

Joint hypermobility

The patient should be assessed for the presence of joint hypermobility. Laxity of the glenohumeral joint in anterior and posterior directions is determined by performing draw tests in which the humeral head is gripped firmly and moved backward and forward in the glenoid fossa. This is best carried out with the patient lying supine and the abducted arm supported by the examiner's hand (Fig. 73.6). Inferior laxity is assessed by applying distal retraction to the arm while palpating the gap between the humeral head and acromion. The presence of a distinct gap can be felt and even seen and is referred to as a positive "sulcus" sign, which is indicative of multidirectional laxity of the joint. Anterior apprehension and stress tests are carried out with the examiner slowly extending and externally rotating the abducted arm with the patient supine. A positive test occurs when the patient experiences pain or apprehension during this maneuver and is confirmed when these symptoms disappear as the examiner's free hand applies a downward (i.e., stabilizing) force to the anterior aspect of the upper part of the humerus. This often allows further external rotation of the arm (Fig. 73.7). Symptoms return as this stabilizing force is slowly withdrawn. It is important to differentiate between a positive test eliciting pain alone and one eliciting apprehension, which may simply indicate internal impingement as opposed to true instability. A posterior stress test is carried out by applying gentle axial pressure on the humerus with the arm in the forward-flexed, internally rotated, and slightly adducted position, again in an attempt to reproduce pain and apprehension.

DIFFERENTIAL DIAGNOSIS OF SHOULDER PAIN

Shoulder pain typically arises from disorders affecting the shoulder joint or periarticular structures but can also be referred from other sites.

Fig. 73.7 Stress test for anterior glenohumeral instability. (a) The examiner slowly extends and externally rotates the abducted arm. (b) Containment sign. Applying pressure anteriorly relieves the symptoms and allows further external rotation.

The glenohumeral joint may be affected in a polyarthropathy such as rheumatoid arthritis or in isolation by conditions such as septic arthritis, neuropathic (Charcot) arthritis, osteonecrosis, and idiopathic destructive arthritis. Articular disorders of the shoulder may be accompanied by swelling, and invariably it has an effect on passive and active glenohumeral motion, with pain, restriction of movement, and often crepitus occurring.

Periarticular conditions affecting the shoulder can be loosely grouped into those with and without capsulitis. If no capsular involvement is present, passive joint motion is largely unaffected, whereas active movement may be limited by pain or weakness (e.g., rotator cuff disorders). Capsulitis causes multidirectional restriction of passive motion, and differentiation from articular conditions of the shoulder is made on clinical and radiologic grounds.

Referral of pain to the shoulder can occur with cervical disorders, Pancoast tumor of the lung, subphrenic pathology, entrapment neuropathies, and brachial neuritis. In these conditions passive and often active movements of the shoulder are largely unaffected, and usually little or no pain occurs when testing rotator cuff function. However, cervicobrachial pain is often associated with painful restriction of passive and active shoulder motion and may be confused with adhesive capsulitis. Differentiation from disorders of the shoulder is possible with an adequate history and examination (Table 73.1).

ROTATOR CUFF TENDINOPATHY

The term *tendinitis* is commonly used to describe patients with a painful tendon condition, although the classic inflammatory reaction is usually absent, especially in those with chronic tendinopathy. The spectrum of disorders affecting the rotator cuff ranges from mild transient tendinitis following an episode of glenohumeral instability in a young patient to a complete tear in the degenerative rotator cuff of an older patient. Subacromial impingement is not always present and can be a cause or result of rotator cuff dysfunction but is not in itself a clinical diagnosis, and it is important to appreciate that different pathologies can be accompanied by symptoms and signs of impingement.

Etiology

A number of extrinsic and intrinsic factors are involved in the etiology of rotator cuff tendinopathy. The anatomic configuration of the shoulder joint is such that the cuff is subjected to stress when the arm is in the elevated position. Impingement can occur as the supraspinatus tendon is compressed between the humeral head and the overlying anterior acromion, coracoacromial ligament, and even the inferior border of the acromioclavicular joint. Impingement may be structural secondary to the presence of an acromial spur or degenerative acromioclavicular joint, but it may also be functional and be caused by superior migration of the humeral head during abduction and elevation.⁴ Mechanical impingement by the coracoid process on the rotator cuff or rotator interval has also been recognized as a clinical entity, although the diagnosis can be confidently confirmed only at the time of surgery.⁹ Underlying glenohumeral instability can result in macrotrauma or microtrauma involving the rotator cuff and is a frequent cause of tendinopathy, particularly in a younger patient, as is eccentric overload in a throwing athlete, in whom the rotator cuff muscles act as decelerators of the throwing arm.

Pathology

As the rotator cuff becomes inflamed, thinned, or torn, its function as a humeral head depressor is compromised, and superior migration of the humeral head can occur through the unopposed action of the deltoid and give rise to further impingement. In a degenerative cuff with a complete tear this can eventually result in cuff arthropathy with osteoarthritis at the subacromial and glenohumeral joints. Impingement leads to inflammation of the subacromial bursa, but this is a reactive process and usually a secondary phenomenon, although primary subacromial bursitis can result from trauma.

Impingement has been shown to occur in forward flexion when the anterior margin of the acromion impinges on the supraspinatus tendon. Vascular studies have demonstrated a constant area of avascularity, or a "critical zone," extending from a point approximately 1 cm proximal to the point of insertion of the tendon into the greater tuberosity, and this compromised microvasculature is seen with the arm in the adducted (neutral) position.¹⁰ However, Iannotti and colleagues¹¹ detected substantial blood flow in this critical zone with laser Doppler, and the use of power Doppler has demonstrated hyperemia in acute tendinopathy. It has long been supposed that this region of relative hypovascularity is compromised during

elevation and abduction, thereby producing an inflammatory response and subsequent tendinitis. The bicipital tendon is frequently involved as part of this condition but is not usually the primary pathology. The pathology of this impingement syndrome was classified by Neer into three stages, but his initial proposal that rotator cuff tendinopathy resulted from subacromial impingement is an oversimplification of the pathogenesis of rotator cuff disease because both extrinsic and intrinsic mechanisms are clearly involved.¹²

Histologic studies have shown that degenerative changes are more prominent on the articular surface of the rotator cuff insertions,¹³ and a number of radiologic studies have confirmed the relative incidence of bursal, articular surface, intrasubstance, and lamination tears of the rotator cuff.

There appears to be progressive tendon failure leading to cuff rupture, with the prevalence of cuff tears increasing with age in the asymptomatic population.¹⁴ Full-thickness tears have been reported in 20% to 30% and partial-thickness tears have been found in a further 20% to 30% of people older than 60 years, with the prevalence of full-thickness tears rising to 50% in those older than 70. Possible etiologic factors include trauma, attrition, ischemia, and impingement, and a number of studies have looked at biochemical changes within the tendon matrix that may predispose to tendon rupture.¹⁵⁻¹⁸

The role of intrinsic factors in the pathogenesis of tendinopathy is becoming better understood. Recent studies have looked at various biologic factors, such as gene expression of growth factors and cytokines and their role in rotator cuff tendon degeneration. Increased matrix metalloproteinase (MMP) activity has been associated with degenerative tendinopathy and rotator cuff disease, and a number of cytokines and growth factors, including basic fibroblast growth factor, bone morphogenetic proteins, platelet-derived growth factor, and transforming growth factors, have been identified and may modulate tendon healing.¹⁹ This has led to the increased use of plasma- and platelet-derived growth factors in the biologic treatment of tendinopathy, although to date there is little evidence that such factors improve clinical outcomes and no consensus has been reached regarding the optimal concentration of platelets and leukocytes that should be administered.

History

The clinical findings depend on the age of the patient and the probable cause. Tendinopathy resulting from eccentric overload or glenohumeral instability in a young adult usually develops acutely following an activity such as throwing. In a middle-aged individual the onset may be more gradual and reflect the underlying chronic changes seen in the involved tendon. The patient may have aching and discomfort in the shoulder, pain on movement, and a history of repetitive or strenuous upper limb activity. An elderly patient may not have any history of antecedent trauma or repetitive activity, and there is usually a gradual onset of increasing shoulder discomfort, night pain, pain with movement, and weakness if a degenerative tear is present. Except for young patients with a history of explosive arm activity or trauma, the onset tends to be gradual and aggravated by movements such as abduction and elevation or sustained overhead activities, which are commonly sports or occupation related. Patients frequently complain that they have difficulty reaching up behind their back when dressing. The pain at night generally occurs when lying on the affected side and is typically felt in the deltoid region rather than the point of the shoulder. Active movements may be restricted by pain, and in more chronic cases secondary capsulitis can develop, thus further restricting movement at the shoulder.

Examination

Findings on examination include a painful arc of abduction usually occurring between 70 and 120 degrees. When lowering from full abduction, there is often a painful "catch," generally at midrange as impingement occurs and particularly in those with associated scapular dyskinesis. Passive motion tends to be full and pain free if adequate muscle relaxation can be achieved. Point tenderness over the greater tuberosity and distal rotator cuff may be present. The diagnosis is confirmed by reproduction of pain when resisting movement of the arm by the affected tendon and with impingement testing. In an older patient, arthritis of the acromioclavicular joint is often present, and there may be early joint stiffness. The probability of an underlying cuff tear increases with age.

Investigations

Plain radiographs may show evidence of rotator cuff degeneration, such as cystic and sclerotic changes at the greater tuberosity insertion, and calcification in the rotator cuff tendons may be seen in chronic

TABLE 73.1
Differential diagnosis of shoulder pain: clinical and radiographic features of common causes of shoulder pain

Diagnosis	Age	Type of onset	Location of pain	Night pain	Active range of motion	Passive range of motion	Impingement signs	Radiation of pain	Paresthesia	Weakness	Instability	Radiographic changes	Special features
Rotator cuff tendinitis	Any	Acute or chronic	Deltoid region	+	↓↓ guarding	Normal	+++	—	—	Only due to pain	Look for	In chronic cases	Painful arc of abduction
Rotator cuff tears (chronic)	>40 yr	Often chronic	Deltoid region	++	↓↓↓	Normal (may ↓ later)	++	—	—	++	—	+	Wasting of cuff muscles
Bicipital tendinitis	Any	Overuse	Anterior	—	↓ guarding	Normal	+	Occasionally into biceps	—	Only due to pain	Look for	None	Special examination tests
Calcific tendinitis	30–60 yr	Acute	Point of shoulder	++	↓↓↓ guarding	Normal except for pain	+++	—	—	Only due to pain	—	++	Tenderness ++
Capsulitis (“frozen shoulder”)	>40 yr	Insidious	Deep in shoulder	++	↓↓	↓↓	+	—	—	—	—	—	Global range of motion ↓
Acromioclavicular joint	Any	Acute or chronic	Over joint	Lying on side	↓ full elevation	Normal	—	—	—	—	—	In chronic cases	Local tenderness
Osteoarthritis of glenohumeral joint	>40 yr	Insidious	Deep in shoulder	++	↓↓	↓↓	—	—	—	May have mild	—	+++	Crepitus
Glenohumeral instability	Usually <25 yr	Episodic	Anterior or posterior	—	Only apprehension	Only apprehension	Possible	—	+ with acute episodes	+ with acute episodes	+++	Often	Stress tests
Cervical spondylosis	>40 yr	Insidious	Suprascapular	Often	Normal	Normal	—	++	+++	+	—	In cervical spine	Pain with neck movement
Thoracic outlet syndrome	Any	Usually with activity	Neck, shoulder, arm	—	Normal	Normal	—	++	++	++	—	—	Special examination tests

cases. Ultrasonography (US) and MRI can be used to identify rotator cuff tendinosis and partial tears, but in the case of US, interpretation is fairly observer dependent. Dynamic US can also demonstrate bunching of the subacromial bursa and impingement.

Differential diagnosis

Pain felt in the deltoid may suggest referred cervical pain, although such pain is more likely to be suprascapular pain referred down the arm. Pain on active movement and impingement testing with preservation of passive motion will differentiate rotator cuff tendinopathy from capsulitis. In cases of tendinopathy caused by underlying instability—which must be suspected in patients younger than 25 years—examination should confirm increased glenohumeral laxity and possibly symptomatic instability.

Management

Treatment of rotator cuff tendinopathy is difficult with continued participation in aggravating activities. Rest and modification of activities are necessary to prevent the problem from becoming chronic. Initial treatment should be directed at reducing inflammation when present with nonsteroidal anti-inflammatory drugs (NSAIDs). Little evidence supports the use of modalities such as US or laser,²⁰ although some evidence does support the use of extracorporeal shock wave therapy (ESWT) in the management of tendinopathy. When such means fail to resolve the symptoms and there is clinical and ultrasonographic evidence of subacromial bursitis or impingement, subacromial injection of corticosteroid can be used (see Chapter 69) while taking care to not inject the rotator cuff directly. A Cochrane review concluded that although such injections may be beneficial, their effect may be small and not well maintained.²¹ Subacromial injection of sodium hyaluronate has been suggested as an alternative treatment of rotator cuff lesions.²²

As well as reducing pain, treatment should be directed at restoring range of motion and the normal biomechanics of shoulder movement while paying particular attention to scapulohumeral rhythm. This is especially important in cases in which such a disturbance in biomechanics has aggravated or even precipitated the problem. Proprioceptive taping can be used to assess the role of scapular dyskinesis in the genesis of dynamic subacromial impingement and is a useful tool in the early rehabilitation of shoulder dysfunction. Once the pain has been reduced and normal shoulder, especially scapulohumeral, movement patterns have been restored, a strengthening program concentrating on rotator cuff exercises should be instituted to restore its function as a humeral head stabilizer and depressor, thereby reducing the likelihood of further injury. A review of level 1 and 2 studies in the literature has found that exercise is effective in reducing the pain in rotator cuff tendinopathy and impingement syndromes and that its effect may be augmented with manual therapy.²³ A younger patient with instability needs a comprehensive rehabilitation program and rarely requires injections in the shoulder. An older patient with a degenerative rotator cuff and associated acromioclavicular joint pathology may be resistant to conservative treatment.

Indications for surgery vary according to the age of the patient, stage of impingement or tendinopathy, and symptoms. The major indication is pain, and in the presence of an intact rotator cuff, failure to respond to a conservative program within 1 year is a reasonable indication for surgery. Surgery involves subacromial decompression and may consist of anterior acromioplasty with or without resection of the coracoacromial ligament, both of which can be carried out arthroscopically. Any impingement secondary to acromioclavicular joint pathology must also be addressed at surgery. The results of subacromial decompression have generally been reported as being good or excellent. However, there is a significant body of opinion that impingement usually results from a disturbance in normal glenohumeral kinematics attributable to capsular tightness, instability, scapulohumeral dysfunction, or loss of rotator cuff function as a humeral head stabilizer. In some cases, preservation of the coracoacromial arch is considered important in maintaining humeral head stability. Therefore, accurate clinical diagnosis and evidence of impingement at surgery are important in determining outcomes following subacromial decompression. In some patients, a capsular release or stabilization procedure may be more appropriate. In other words, subacromial impingement is frequently the result rather than the cause of shoulder dysfunction, and some think that decompression has little place as a stand-alone procedure.

Prevention

In a young patient or athlete, attention to proper preparation for exercise and correct technique is important. In many athletes, muscular imbalances

about the shoulder develop through either tightness or weakness, and secondary impingement and tendinopathy can result if these imbalances are not corrected. Serratus anterior fatigue results in loss of scapular stability and can lead to subacromial or internal impingement. In an older patient, avoidance of sustained above-shoulder activities or explosive lifting will help prevent this condition from deteriorating or perhaps even developing.

ROTATOR CUFF TEARS

Pathology

The incidence of degenerative cuff tears increases with age, as does the size of the tear.²⁴ Cuff tears are widely variable in type and extent. Full-thickness tears in one component of the rotator cuff often coexist with partial or intrasubstance tears in another area. Classification of the size and age of the tear, as well as the extent of tear retraction and fatty atrophy of the muscle belly, is important in planning treatment and predicting surgical outcomes. Superior migration of the humeral head against the undersurface of the acromion occurs as the incompetent rotator cuff fails to stabilize and depress the humeral head and therefore counteract the pull of the deltoid. This leads to degenerative changes both at the subacromial joint and secondarily at the glenohumeral joint, known as rotator cuff arthropathy. Neer estimated that 4% of cuff tears ultimately progress to cuff arthropathy,²⁵ although the true figure is probably greater.

Clinical features

Rotator cuff tears may be acute or chronic, partial or full thickness. Partial tears may occur in any age group following trauma, but a full-thickness tear is uncommon in patients younger than 40 years. In a young adult a partial tear can result from a fall or explosive shoulder movement and is manifested very much as an acute tendinopathy. Also, full active range of motion may be preserved. An acute complete rupture after trauma should be diagnosed readily. The mechanism of injury is usually a fall onto an outstretched arm, a hyperabduction injury, or a fall onto the side of the shoulder. Bruising is often delayed and occurs in the upper part of the arm, and there is usually immediate loss of active abduction and weakness of abduction and external rotation. Dislocation of the shoulder in patients older than 40 years is closely associated with partial or complete tears of the rotator cuff. In one review of 40 patients the prevalence of full-thickness tears was 90%.²⁶

Previous studies have recorded the incidence of chronic full-thickness tears found at autopsy,²⁷ although more recent MRI studies have reported a greater prevalence in the asymptomatic population, and many patients with a documented complete tear of the supraspinatus tendon have full active abduction, often in the absence of pain and even in the presence of abnormal glenohumeral kinematics and superior humeral head migration.²⁸ There may be no history of trauma, and symptoms frequently become apparent with increased activity, although the clinical expression of rotator cuff tears is variable.²⁹ The usual picture is pain on abduction and flexion with varying degrees of loss of active movement, depending on the size of the tear and the ability of the remaining rotator cuff to stabilize the humeral head. The patient may complain of weakness of abduction, flexion, and internal or external rotation, depending on the tendon involved.

Night pain is common and often severe. Examination reveals many of the features of rotator cuff tendinopathy, but the patient is often unable to maintain the arm in abduction when lowering from the elevated position (i.e., a positive “drop-off” sign). Subacromial crepitus and pain on impingement testing are usually present. A common clinical finding is wasting of the infraspinatus and supraspinatus muscle bellies, together with weakness of abduction, but more often weakness of external rotation reflects the size of the tear. Isometric measurement of rotation strength correlates well with the functional integrity of the rotator cuff, along with the patient's function and quality of life.³⁰ Rupture of the long head of the biceps tendon is frequently associated with chronic rotator cuff pathology.

Investigation

Features of chronic rotator cuff degeneration along with sclerosis and cystic changes at the greater tuberosity can be seen on plain radiography. Spur formation may be present along the anterior inferior acromion, often with osteoarthritis of the acromioclavicular joint. With a complete tear there may be superior migration of the humeral head and narrowing of the subacromial space (less than 6 mm indicates a tear). This finding, along with degenerative change, is seen in cuff arthropathy.

Fig. 73.8 Ultrasound of an acute full-thickness rotator cuff tear.

Fig. 73.9 Magnetic resonance image of a complete rotator cuff tear. The image shows a full-thickness tear of the distal supraspinatus tendon with early retraction of the articular side of the tendon.

Full-thickness tears are readily demonstrable with single- or double-contrast arthrography, with a sensitivity approaching 90%. Partial tears can occasionally be seen. However, estimation of the size of the defect with arthrography is unreliable, and it is rarely used unless in conjunction with computed tomography (CT) or MRI. US can identify and size tears, both full- and to a lesser extent partial-thickness tears (Fig. 73.8). MRI compares favorably with arthrography in the diagnosis of complete tears (Fig. 73.9). It is less consistent in the assessment of partial and lamination tears (Fig. 73.10) but allows assessment of tear retraction, muscle atrophy, and fatty degeneration in the rotator cuff muscles, which is important in the selection of patients for surgery. Arthroscopy may be used to establish the diagnosis in a patient with shoulder pain who requires further assessment. It is particularly useful in the assessment of instability while at the same time allowing visualization of the rotator cuff, subacromial bursa, intraarticular bicipital tendon, and glenoid labrum. It also allows estimation of the size of a tear before more definitive surgery, although cuff repairs are increasingly being performed arthroscopically.

Management

Initially, partial rotator cuff tears should all be managed conservatively, as for tendinopathy, although corticosteroid injection is not advisable within 4 to 6 weeks of an acute injury and there is less support for its use given the pathogenesis of tendinopathy. Growth factors and other biologic treatments are increasingly being administered, but evidence for their use is inconclusive. Despite the current lack of evidence, platelet-rich plasma and platelet-derived growth factors are often used to augment cuff repairs, and extracellular matrix scaffolds can be used as a means of delivery. Bursal and

articular surface tears may be amenable to arthroscopic débridement, decompression, and possibly repair, but intrasubstance and laminar tears are best treated nonoperatively unless associated with subacromial impingement. Surgical management of partial or small full-thickness tears is somewhat controversial, and no consensus has been reached on when to intervene in these patients. Acute ruptures in a young or active patient should be managed surgically earlier rather than later. In an older or less active patient a trial of conservative management is reasonable, but if no substantial improvement occurs within 3 months, subacromial decompression with cuff repair is advisable.

Chronic complete tears are usually treated with an adequate conservative program initially. Failure to achieve pain relief is a major indication for surgical intervention. Any operative procedure should be directed primarily at relief of impingement, débridement of the cuff tear, and usually, but not always, repair of the defect. Surgery should also be considered in those with an associated rupture of the biceps tendon because cuff arthropathy appears to be more likely to develop in these cases, although in some patients bicipital tendinopathy is the primary pain generator and spontaneous rupture of the biceps tendon can lead to significant pain relief. Therefore some surgeons advocate biceps tenotomy when performing a cuff repair.

The results of surgical repair of rotator cuff tears are generally good but depend on the age of the patient and the size and age of the tear. Pain relief is usually achieved, but recovery of strength is less predictable and restoration of joint motion may depend on the amount of postoperative stiffness that develops. A major predictor of outcome following repair is the degree of rotator cuff muscle atrophy and fatty infiltration, which can be assessed preoperatively with CT or MRI.³¹ Therefore, a number of factors must be taken into account when deciding whether to proceed to surgery, including the patient's age and occupation, the size and type of tear (repair of lamination and complex tears can be difficult), and the degree of tendon retraction and muscle atrophy. Surgery should be delayed in patients with associated capsulitis, and capsular release may be required beforehand. Full-thickness tears of the subscapularis are best repaired early because delayed closure may not be possible once the torn tendon has retracted. With large or massive retracted tears, latissimus dorsi or pectoralis major muscle transfer may be required to close the defect and improve function, but other surgical options include simple débridement and decompression or partial repair with a residual defect remaining. However, for many of these patients the best option is total shoulder arthroplasty with a reverse prosthesis if the symptoms and loss of function warrant intervention.

OTHER PERIARTICULAR DISORDERS

Bicipital tendinitis

Pathology

The tendon of the long head of the biceps may be involved at several sites: at its attachment to the superior glenoid labrum, which may be injured in a fall or throwing action (SLAP lesion³²); as it runs across the glenohumeral joint (intraarticular), where it is stabilized by a pulley system made up of

the coracohumeral ligament, SGHL, and fibers of the supraspinatus and subscapularis tendons; or as it runs in the bicipital groove (extraarticular). The transverse humeral ligament stabilizes the tendon in the bicipital groove, and if this mechanism is disrupted, subluxation or dislocation of the tendon can result. This tends to occur as the arm is rotated in the abducted position. The tendon can become inflamed, thickened, and fibrotic in chronic cases, and it has been shown that bicipital groove anatomy correlates with biceps tendon disease.³³ In an older patient, attenuation and thinning of the tendon and eventual rupture may occur. The latter is almost always indicative of underlying rotator cuff degeneration because the bicipital tendon appears to become stressed in its attempt to act as a humeral head depressor in cases of rotator cuff incompetence. In addition, the presence of a complete rotator cuff tear exposes the intraarticular portion of the bicipital tendon to the overlying acromion and further impingement.

Clinical features

Though diagnosed frequently, bicipital tendinitis does not often develop in isolation and usually occurs in association with rotator cuff tendinopathy or impingement or with glenohumeral instability. Primary involvement of the tendon is seen as an overuse injury in sports such as weightlifting, where repetitive stress is placed on the tendon, or after prolonged and repetitive carrying (e.g., of small children). The bicipital tendon acts as a secondary stabilizer of the humeral head, and the translational movement seen with glenohumeral laxity can place increased stress on the tendon and thereby lead to tendinitis. As with rotator cuff tendinopathy, a young patient with bicipital tendinitis should be assessed for instability. With chronic impingement or rotator cuff degeneration, the biceps tendon may become fibrotic and attenuated and eventually rupture. Acute ruptures are also seen in young powerlifters.

Pain is generally felt over the anterior aspect of the shoulder and frequently radiates to the biceps muscle, and there is tenderness over the tendon as it runs in the bicipital groove. Pain is felt with overhead activities and often with shoulder extension and elbow flexion. Examination may reveal features of impingement, rotator cuff tendinopathy, and instability, all of which are important in the etiology of bicipital tendinitis. Pain may be reproduced with resisted elbow flexion, supination, and shoulder flexion, and various provocation tests have been described, although none appears to be consistently positive. Passive shoulder extension stretches the biceps and may be painful. Rupture of the tendon is characterized by bunching up of the lateral muscle belly of the biceps, which is best seen with resisted elbow flexion and supination.

Acute rupture of the transverse humeral ligament can result in subluxation or dislocation of the tendon. This can cause symptoms similar to bicipital tendinitis, and the patient usually complains of catching and a clicking sensation at the shoulder. Clinical examination may demonstrate subluxation of the tendon, which is felt as the arm is passively moved through internal and external rotation while in the 90-degree abducted position. Medial dislocation of the tendon is generally associated with tears of the subscapularis tendon.

Investigation

Special radiographic views demonstrate the bicipital groove and allow assessment of its depth and the presence of any hypertrophic spurring. Filling of the synovial extension around the tendon is seen on arthrography and may be reduced in cases of chronic fibrosis. The tendon and any surrounding fluid can be seen well with US (Fig. 73.11), and this assists in the diagnosis of tears, both partial and complete, as well as tendinitis. It can also be used to demonstrate subluxation or dislocation of the tendon. MRI or arthroscopy allows visualization of the intraarticular portion of the tendon and its labral attachment (Fig. 73.12).

Management

It is necessary to establish whether the tendinitis is primary or secondary because failure to address any underlying rotator cuff pathology or instability will lead to recurrence of symptoms. The principles of management are rest, physical modalities, and NSAIDs as required. Low-power laser therapy has been reported to have a beneficial effect, although this has been disputed.³⁴ Corticosteroid injection is helpful in chronic cases, but care should be taken to not inject the tendon itself. An intraarticular injection or injection into the tendon sheath may be given, but both are best done under US guidance. Because most cases of bicipital tendinitis are secondary, they usually resolve as the primary condition is treated. The primary cases caused by lifting or other activities may respond to rest and antiinflammatory measures. Surgery can be considered in chronic, resistant cases and may involve subacromial decompression in cases of impingement or tenodesis when there is chronic thickening of the tendon in the groove. Rupture of the

Fig. 73.11 Ultrasound of bicipital tendinitis. A transverse image shows a large effusion (arrows) in the long head of the biceps tendon sheath.

Fig. 73.12 SLAP (superior labrum anterior to posterior) type 2 lesion. A nonarthrographic coronal proton density magnetic resonance image demonstrates a tear (arrow) at the base of the superior labrum involving the biceps anchor.

tendon is normally treated conservatively except in occasional young patients in whom upper arm strength is critical to their sport or profession. Usually, weakness following this injury is not significant. Subluxation of the tendon is often treated conservatively, although surgery is occasionally necessary, and medial subluxation or dislocation of the tendon out of the groove generally indicates the presence of a tear in the subscapularis tendon, which may not be apparent on US.

Any conservative program must include range-of-motion exercises, stretches, and once the symptoms have settled, a graduated eccentric and concentric biceps and rotator cuff strengthening program while ensuring that any instability or scapular dyskinesis is addressed.

Subacromial bursitis

In most cases, inflammation of the bursa arises as part of the impingement process and coexists with an underlying rotator cuff tendinopathy. This bursitis is therefore a reactive phenomenon. In chronic cases the bursa becomes thickened and fibrotic and surgical excision or débridement may

be necessary. Treatment of rotator cuff tendinopathy is directed at reducing inflammation in the subacromial bursa, as well as reducing impingement.

Acute traumatic bursitis in the form of hemorrhage and edema can occur as a result of a fall on or a direct blow to the point of the shoulder. Pain on abduction is present, but differentiation from rotator cuff tendinopathy is possible on the basis of increased tenderness and fluid in the subacromial space. A period of rest combined with simple measures such as the application of ice usually allows resumption of normal activities, but persistent impingement occasionally develops and require further treatment.

Capsulitis

Definition

Capsulitis of the shoulder remains a condition both difficult to define and universally awkward to manage. Many labels have been given to the situation in which painful restriction of shoulder movement is apparently of soft tissue origin, including frozen shoulder, peri arthritis or pericapsulitis of the shoulder, adhesive capsulitis, and adherent or obliterative bursitis. There has been an attempt to classify patients with a painful stiff shoulder according to the presence or absence of capsular joint restriction as seen with arthrography.³⁵ Perhaps incorrectly, the term “frozen shoulder” is applied to many conditions in which restriction of movement is largely due to pain from an underlying condition, such as rotator cuff tendinopathy, rather than caused by the classic global restriction of glenohumeral joint motion seen with true adhesive capsulitis.

Primary capsulitis of the shoulder can be defined as a condition of unknown etiology in which glenohumeral movement is painfully restricted in all planes of motion, both active and passive, in the absence of joint degeneration sufficient to explain such restriction. A similar condition known as secondary capsulitis exists when the condition is associated with a clearly defined clinical disorder or precipitating event.

Pathology

The etiology of adhesive capsulitis is not known. There is some evidence of its association with a number of conditions, including diabetes mellitus, thyroid disease, hyperlipidemia, pulmonary disorders such as tuberculosis or carcinoma, cardiac disease or surgery, cerebrovascular accident, and particularly shoulder trauma. The evidence for such associations, however, is generally unconvincing. Dupuytren disease is often seen in association with adhesive capsulitis, and it has been suggested that the two conditions may have similar biochemical and histologic characteristics.³⁶ Following traction or hyperabduction injuries to the shoulder, a mixed clinical picture of capsulitis and cervicobrachialgia may develop, thus further complicating diagnosis and treatment.

Capsulitis is more prevalent in patients with diabetes (prevalence of 10% to 20%), usually occurs at a younger age, and is often associated with a prolonged duration of diabetes, insulin dependence, the development of limited joint mobility syndrome, and widespread microvascular disease. Bilateral involvement is also more common in diabetes. The links between diabetes and capsulitis may revolve around microvascular disease, abnormalities in collagen repair, or predisposition to infection.³⁷ An association between capsulitis and thyroid disease and pulmonary conditions has been noted but provides little information regarding its pathogenesis. Histologic studies have failed to demonstrate the presence of inflammatory cell infiltrates, granulomas, or vasculitis in the joint capsule or synovium. Also, nothing has been found to implicate infection, crystal arthropathy, or trauma.

Histologic studies of the joint capsule early in the disease are difficult to perform, and the heterogeneity of patients loosely labeled as having capsulitis makes study of this condition problematic. Lundberg noted an increase in fibrous tissue, fibroblast number, and vascularity with no change in the synovial lining and no inflammatory cell infiltrate.³⁸ Bunker and Anthony reported that fibroblasts and myofibroblasts lay down a dense type III collagen matrix in the shoulder joint capsule that leads to joint contracture.³⁹ Cytokine, MMP, and MMP inhibitor abnormalities have been reported, and it has been proposed that increased production of growth factors is the central precursor to capsular fibrosis.⁴⁰ Several studies have looked at a variety of immunologic factors, but no immunologic disturbance has been demonstrated.³⁷

Clinical features

Estimation of the prevalence of adhesive capsulitis is difficult because of variation in the populations studied and the diagnostic criteria used, but it appears to be approximately 2% to 3% in those without diabetes. Onset in those younger than 40 years is rare, with the mean age at onset being in the sixth decade. Women are affected more often than men. Involvement of the contralateral shoulder occurs in 6% to 17% of patients over the subsequent

5 years.³⁷ It is commonly stated that recurrence in the same shoulder does not take place. Patients frequently relate a history of minor shoulder strain or injury before the onset of symptoms, but whether this represents a true strain of the shoulder or simply the earliest awareness of pain is unclear.

The natural history of adhesive capsulitis has been described by various authors, and it appears that there are three phases in its development and progression. The shoulder moves from being simply painful to being painful and stiff and eventually to being less painful but profoundly stiff. This last stage appears to be self-limited, and recovery is gradual and spontaneous. These phases have been termed *painful*, *adhesive*, and *resolution*. The duration of each phase in the overall condition varies considerably, but approximate durations are 3 to 8 months for the painful phase, 4 to 6 months for the adhesive phase, and 1 to 3 years for the resolution phase. The extent of recovery is variable, with quoted figures of 33% to 61% of patients having a clinically detectable limitation of shoulder movement, and although many remain asymptomatic, 7% to 15% of patients may have a persistent functional disability.³⁷ The extent to which the duration of the painful and adhesive phases determines the degree of residual disability remains controversial. It does appear that capsulitis in a patient with diabetes runs a more protracted course with marked stiffness and less complete recovery.

Painful phase

This phase is characterized by the insidious onset of symptoms, usually in the form of pain on shoulder movement and background ache in the shoulder, typically in the suprascapular and deltoid regions. Frequently, patients are treated as for rotator cuff tendinopathy and subacromial bursitis, which is often noted on US. As the condition becomes established, the pain increases during rest and at night, the latter becoming quite disturbing and frequently waking the patient in the absence of a history of precipitative movement. Muscle spasm may develop and further limit shoulder movement, which becomes restricted with the increase in pain and stiffness at the shoulder. Toward the end of this phase stiffness becomes a major complaint.

Adhesive phase

Usually after several months the character of the pain alters and becomes less severe. The pain during rest and at night is reduced, but discomfort and more severe pain at the limits of motion persist. Shoulder movement becomes more restricted during this phase, which can lead to periscapular pain because of the increase in scapulothoracic motion.

Resolution phase

Pain is less evident and the dominant symptom is restriction of movement, which is less distressing for the patient now that the pain has eased. Range of motion improves slowly and gradually, although it is frequently incomplete. The onset and rate of recovery are variable and unpredictable.

Clinical examination

The physical signs change as the condition progresses, with pain, often severe, being present in the earlier stages. Differentiation from symptomatic rotator cuff tendinopathy is possible on the basis of global restriction of passive movement rather than simply the loss of abduction and flexion that is seen with chronic rotator cuff conditions. A useful early clinical indicator of developing capsulitis is pain at the limit of passive external rotation of the shoulder with the arm by the side. In the painful phase there is painful restriction of active and passive motion (often mild in the earlier stages). Pain may occur during impingement testing and resisted movement, although this is less common than in rotator cuff tendinopathy. Associated findings are tenderness in the upper trapezius muscle and early scapula hitching in elevation. In some patients the pain can be severe enough to necessitate opioid analgesia, and the clinician may feel the need to exclude other causes such as avascular necrosis or neoplastic disease. Indeed, shoulder tumors may be manifested as capsulitis. In the latter phases the important finding is significant restriction of glenohumeral movement with a compensatory increase in scapulothoracic motion during flexion and abduction. Pain may be present, but there is less discrepancy between active and passive ranges. Disuse atrophy of the rotator cuff and deltoid muscles may exist. Joint line tenderness may be present in the painful phase.

Investigation

The diagnosis is made largely on clinical grounds because few abnormalities are found on investigation. Plain radiographs are not helpful in making the diagnosis except to exclude osteoarthritis, calcific tendinitis, or neoplasm. In a younger patient with clinical features of adhesive capsulitis, avascular necrosis should be suspected and must be excluded before considering intraarticular corticosteroid injections.

Classic features on arthrography are limitation of joint volume with loss of the normal dependent axillary fold or pouch and irregularity of the capsular insertion to the anatomic neck of the humerus. Between 10% and 30% of patients who undergo arthrography have a demonstrable complete tear of the rotator cuff. Other studies have suggested that a significant number of patients with a clinical diagnosis of adhesive capsulitis have normal findings on arthrography.⁴¹ Arthroscopy allows further evaluation of these patients, and different stages of synovitis and contracture have been described.³⁵

Bone scintigraphy may demonstrate increased uptake of isotope in the affected shoulder region, but this appears to have no predictive value in terms of outcome or response to treatment and is therefore of limited diagnostic value.⁴¹ An average reduction in bone mineral content of 50% in the affected humeral head has been demonstrated, although this is also of little diagnostic or therapeutic value. US has been performed and typical findings are biceps sheath effusion, restriction of movement, and subacromial impingement resulting from the capsular contracture, but these features are not diagnostic and patients are often mistakenly treated for impingement. Indeed, failure to respond to treatment and early loss of joint motion should alert the clinician to the possibility of capsulitis developing. MRI may be indicated to exclude other causes of shoulder pain but is not generally required. However, some features on MRI, including signal change and scarring in the rotator interval, as well as hyperintensity and capsular thickening of the axillary pouch, appear to correlate with the clinical stages of adhesive capsulitis⁴² (Fig. 73.13).

Management

Many therapies have been used in an attempt to modify the natural history of capsulitis, but clinical studies of the efficacy of various treatment methods have been compromised by difficulties in patient selection and diagnostic criteria and variability in natural resolution of the condition. The emphasis of treatment in the early stages should be on reduction of pain and minimization of joint restriction. Analgesics and antiinflammatory drugs provide limited relief of pain but do little to alter the course of the disorder. Physiotherapy uses physical modalities to modify pain and reduce protective muscle spasm while attempting to encourage early range-of-motion exercises for maintaining joint mobility. Shoulder immobilization should be discouraged, although in the painful phase the patient tends to minimize shoulder movement.

Few treatments have been shown to consistently affect the rate of recovery or limit the restriction of movement. Intraarticular corticosteroid injections are commonly used and have been shown to reduce pain and disability for upward of 3 months, although no long-term benefit has been demonstrated.⁴³ The addition of supervised physiotherapy appears to provide faster improvement in range of joint motion. Intraarticular injection is best done under US guidance or fluoroscopy, and failure to do so in previous studies may account for the variable response to corticosteroid injection in the past. It still remains a useful and often effective means of relieving pain and hastening recovery. Oral corticosteroids have also been shown to improve pain but not to affect the rate of recovery. Careful use of analgesic or anti-inflammatory drugs with physiotherapy may be of benefit, although this may be due to a reduction in the protective spasm seen in untreated patients.

Hydrodistention of the joint capsule has been used for treatment of the various stages of this condition, usually in conjunction with corticosteroid injection, but it is still unclear whether it offers any additional benefit over corticosteroid injection alone. Manipulation under anesthesia has been used to restore joint motion but may result in rupture of the inferior capsule and possibly the subscapularis tendon at its insertion. Care should be taken when carrying out this procedure, especially in elderly patients, to avoid humeral fracture, shoulder dislocation, or a significant rotator cuff rupture. Aggressive early rehabilitation in the immediate postmanipulation period is needed to maintain joint mobility, and patient cooperation and tolerance of this treatment are essential. Manipulation during the painful phase is not recommended because painful recontraction of the capsule may occur, and such treatment is usually reserved for the adhesive phase once the pain has settled.

Nonoperative treatment is effective in the vast majority of cases, but arthroscopic capsulotomy can be used to treat recalcitrant cases of frozen shoulder.⁴⁴ Some authors do not restrict the use of this treatment to patients who no longer have significant pain and advocate arthroscopic capsular release over manipulation because it allows direct visualization of the joint capsule and therefore poses less risk for tendon rupture. For many patients, however, once the painful phase of their condition has subsided, the prospect of this painful procedure is not appealing. Improvement in range of movement following manipulation or capsulotomy is variable and perhaps dependent on patient selection. Long-term recovery appears to be unchanged, although resolution may be accelerated immediately following manipulation.

Fig. 73.13 Nonarthrographic magnetic resonance images of capsulitis. Fat-suppressed images show hyperintense capsular and synovial thickening within the rotator interval (arrows) and diffuse hyperintense thickening of the glenohumeral joint capsule (arrowheads) with an accompanying small joint effusion (asterisk).

ACROMIOCLAVICULAR SYNDROMES

Introduction

Pain localized to the acromioclavicular joint is commonly seen as either an acute or a chronic condition. In a younger patient this joint is frequently subjected to trauma as a result of falls or contact sports, which may result in an acute injury and also predispose the joint to further problems such as instability or secondary osteoarthritis. Atraumatic acromioclavicular joint pain is common and may be difficult to distinguish from other causes of shoulder pain. Infection of this joint is rare, but septic arthritis has been described.

Trauma

Disruption of the acromioclavicular joint may be seen in association with fractures of the outer end of the clavicle and often leads to the development of secondary osteoarthritis. More common are injuries to the joint itself, which are graded according to the degree of disruption of the joint capsule and supporting ligaments.⁴⁵ Grade I injury involves a minor sprain of the joint capsule without ligament disruption. Grade II injury involves subluxation of the joint with downward displacement of the acromion relative to the distal end of the clavicle. The inferior acromioclavicular ligaments are stretched, and there is stretching and possibly a partial tear, but not complete rupture, of the coracoclavicular ligaments. In a grade III injury, complete dislocation of the joint occurs through rupture of the coracoclavicular ligaments. Grade III injuries can be further classified (often as grades IV, V, and VI) according to the extent and direction of disruption or perforation of the overlying deltoid fascia or muscle layer by the displaced outer end of the clavicle.

Clinical features

The mechanism of injury usually involves a fall directly onto the point of the shoulder. Pain is localized to the top of the shoulder in the region of the involved joint, which is tender and often swollen. Abduction is limited, both actively and passively, according to the degree of joint disruption. For a minor injury with good preservation of movement, acromioclavicular joint stress tests can be carried out to localize the symptoms. With complete dislocation of the joint a visible step deformity is seen, and examination will determine whether this dislocation can be reduced. This is important in the differentiation of grade III to VI injuries. The patient often describes a feeling of the shoulder having dropped because of downward displacement of the acromion.

Management

For grade I or II injuries, treatment is largely symptomatic and consists of analgesics and provision of a sling for days to weeks depending on the symptoms. Shoulder movements should be encouraged as the pain settles, and functional recovery is excellent.

Controversy exists over the management of grade III injuries. Provided that perforation of the overlying muscle or fascial layer has not occurred, the injury resolves in most patients over a period of 6 to 10 weeks with conservative treatment. Strapping of the joint has no effect on long-term stability and is not indicated in these patients. Surgical stabilization by means of internal fixation is associated with a significant complication and failure rate, but several procedures involving reconstruction of the coracoclavicular ligaments have been shown to be effective, although the long-term results are not demonstrably better than those with nonoperative treatment. Surgical advances have lowered the complication rate and therefore the threshold for considering surgical repair or reconstruction of the acromioclavicular joint, particularly in manual workers or people dependent on overhead function. However, surgery is usually reserved for severe grade III disruptions or situations in which an individual's occupation may be compromised by persistent deformity or instability at that joint. Acute repair should be performed within 2 weeks of the injury or reconstruction will be required.

Late sequelae

Patients may have persistent pain at the acromioclavicular joint. This represents low-grade joint inflammation and may be associated with underlying instability, early development of secondary osteoarthritis, or osteolysis of the distal end of the clavicle. Persistent pain following joint injury may also result from damage to the intraarticular fibrocartilage sustained at the time of injury. Treatment is symptomatic, with antiinflammatory medication or intraarticular injection of corticosteroid for resistant cases. Delayed surgical stabilization may be carried out in those with gross instability, and tears of

the fibrocartilage can be debrided arthroscopically. Long-term treatment is as for osteoarthritis of the joint.

Osteolysis of the clavicle

Osteolysis of the distal end of the clavicle is a condition that may follow an acute injury or repetitive stress involving the shoulder. The symptoms are similar to those of acromioclavicular inflammation, with aching and pain at the limits of flexion and abduction. Radiographic changes typically include resorption of the distal end of the clavicle, often with osteophyte formation, osteoporosis, or tapering. The response to modification of activity and conservative treatment is usually satisfactory, but excision of the distal part of the clavicle may be necessary. Distal clavicular reconstitution may even occur with rest.

Osteoarthritis

Acromioclavicular joint morphology appears to be associated with the development of osteoarthritis, although cadaveric studies have shown that degenerative changes occur in this joint with normal aging after 40 years of age. A previous history of joint injury is common when osteoarthritis of this joint occurs in isolation, but the joint may also be involved as part of generalized osteoarthritis. Acromioclavicular osteoarthritis is common and frequently asymptomatic.

Clinical features

Pain and tenderness are localized to the joint, which is often prominent because of osteophyte formation. Pain is felt on full abduction or horizontal adduction and can also be reproduced with adduction of the extended arm. Crepitus is frequently localized to the joint. It is important to note that osteoarthritis of the joint is often seen in association with rotator cuff degeneration and that inferior osteophytes at the acromioclavicular joint may contribute to the development of a rotator cuff tear. Clinical features of both conditions frequently coexist, especially in an older patient.

Investigation

Osteoarthritis can be diagnosed with plain radiography. Traction or weight-bearing views can be taken to demonstrate joint instability.

Management

Initial management consists of local modalities and the use of analgesic or antiinflammatory drugs. An exercise program should be prescribed to restore normal scapulohumeral rhythm, glenohumeral range of motion, and deltoid and rotator cuff strength once the symptoms have settled. Intraarticular corticosteroid injection usually provides relief of symptoms but often needs to be repeated. Cases resistant to conservative treatment may require surgery, which consists of excision arthroplasty of the joint while ensuring that instability is minimized. Careful assessment of rotator cuff function is important, and in the presence of a significant tear, rotator cuff repair or acromioplasty may be indicated. Excision arthroplasty may also be indicated in a younger patient with chronic symptoms, whether caused by degenerative change, osteolysis, or instability.

CALCIFIC TENDINITIS

The prevalence of radiologically detectable calcification in the rotator cuff tendons is reported to be 2.7% to 7.5%; it occurs in both symptomatic and asymptomatic shoulders.⁴⁶ Calcific tendinitis commonly involves the supraspinatus tendon and has been reported to be more frequent in women and sedentary individuals. Bosworth⁴⁷ estimated that symptoms develop in 35% to 45% of individuals with calcification seen on radiography. Frequently bilateral, it usually develops between the ages of 40 and 60 years but can occur as an acute condition in a younger patient. Patients may have chronic symptoms of catching pain with movement as a result of impingement.

Acute calcific tendinitis has a quite different manifestation, with acute severe pain limiting passive or active shoulder movement almost completely and exquisite point tenderness and occasionally erythema being present over the involved tendon. The onset of symptoms can be rapid with no history of injury or overuse, and this occurs during the resorptive phase of calcification.

Patients can therefore be divided into two groups: those with an acute onset of severe pain and limitation of movement, often in the absence of any previous shoulder symptoms, and those who have more chronic catching pain associated with movement and features of subacromial impingement.

Pathophysiology

It has been argued by various authors that calcification occurs as part of a degenerative process involving the rotator cuff tendons, largely because it is rarely seen in people before the fourth decade. Also, complete cuff tears have been found in 21% of patients with calcific tendinitis.⁴⁸ Histologic studies have confirmed that calcification occurs following tendon fibrosis and subsequent necrosis. Uhthoff and Sarkar⁴⁶ proposed a model for the pathogenesis of calcific tendinitis based on its clinical findings as a self-healing condition in which the calcific process is actively mediated by cells in a viable environment. They classified the disease into three stages: precalcific, calcific, and postcalcific. In the precalcific stage it is thought that fibrocartilaginous transformation takes place in the avascular, or “critical,” zone of the supraspinatus tendon. In the calcific stage, calcium crystals are deposited in matrix vehicles and form large deposits (known as the formative phase). After a variable period of inactivity (resting period), the calcium is spontaneously resorbed by means of peripheral vascularization and phagocytosis of the deposit (resorptive phase). Following removal of the calcium the space is filled with granulation tissue (postcalcific stage). Occasionally, a deposit can rupture into the overlying subacromial bursa. An association between this condition and HLA-A1 has been reported.⁴⁶

Investigation

A plain radiograph will identify and localize the calcific deposit to a particular tendon, generally the supraspinatus. In the formative phase of calcification the deposit is well defined and homogeneously dense. In the resorptive phase, usually manifested as the acute condition, the deposit is less well defined and irregular and has a fluffy, less dense appearance (Fig. 73.14). However, the type and size of the deposit do not correlate with the severity of symptoms.⁴⁹ Cortical erosion develops in patients in whom the deposit is in contact with bone, and some authors think that there is a subset of patients with osteolytic lesions of the tuberosities in whom the disease runs a more protracted course.⁵⁰ Degenerative rotator cuff disease and arthropathy may have radiologically detectable calcification, but this is usually associated with other features of these conditions, and the areas of calcification are generally small, stippled, and close to the tendon insertion at the greater tuberosity.

Laboratory investigation does not usually reveal any abnormality in calcium or phosphate metabolism. There is no associated leukocytosis, raised erythrocyte sedimentation rate, or change in serum alkaline phosphatase activity.

Management

Asymptomatic patients require no specific treatment, and spontaneous healing occurs in a significant number of patients. In those with chronic symptoms, conservative management consists of mobility and strengthening exercises of the glenohumeral joint, correction of any scapular dyskinesis, physical modalities, and NSAIDs for relief of symptoms if required. A subacromial injection of corticosteroid can be given to those with clear-cut features of impingement and inflammation but should be repeated only with caution. ESWT has been reported to be effective in selected patients. In the acute stages, treatment should include resting the arm in a sling, analgesics,

antiinflammatory medication, and local application of ice. Needling and attempted aspiration of the deposit under US control may result in reduction of pain, and needling may be followed by lavage. Subacromial injection of lidocaine should be done for temporary relief of pain. Injection of corticosteroid may inhibit the resorption of calcium by reducing vascular proliferation and macrophage activity, although it is often administered following needling. Conservative treatment is usually effective in acute cases, but surgical intervention is indicated when nonoperative management of the chronic condition has failed and there are persistent features of impingement. The deposit can be removed arthroscopically and may be followed by resection of the coracoacromial ligament and anterior acromioplasty, although some evidence suggests that these additional procedures are unnecessary and may be associated with a poorer outcome.

GLENOHUMERAL INSTABILITY AND INTERNAL IMPINGEMENT

Glenohumeral instability is a major cause of symptoms and pathology around the shoulder joint. The more traditional orthopedic model of shoulder dislocation, whether acute or recurrent, has been expanded to encompass the more subtle but equally important subluxations and occult instabilities that can play an important role in the development of shoulder pain, especially in a young active population. Glenohumeral instability can be classified according to the etiology, direction, type, and circumstance of the instability, although in reality this represents a spectrum of disorders ranging from traumatic unidirectional dislocation with a Bankart lesion (TUBS) to the atraumatic multidirectional instability resulting from bilateral glenohumeral laxity (AMBRI).⁵¹ Symptomatic subluxation or instability often results in a painful shoulder with the features of rotator cuff or bicipital tendinitis, but a careful history and examination coupled with a high index of suspicion in a young adult should confirm the presence of instability. Patients with instability may have symptoms of a labral tear such as painful clicking and catching. A ganglion cyst arising from the posterior glenoid labrum in patients with underlying posterior instability may lead to compression of the suprascapular nerve at the spinoglenoid notch, which causes such patients to occasionally have significant weakness in external rotation (Fig. 73.15).

In a throwing athlete, adaptive changes such as stretching of the anterior capsule and contraction of the posterior capsule provide an increased range of external rotation and reduced internal rotation, which allows higher throwing velocity. There is also evidence of adaptive change in the humerus and glenoid (increased retroversion)⁵² giving rise to asymmetric rotation between the dominant and nondominant shoulder. As a result of such changes or in athletes with occult instability, increased glenohumeral rotation and angulation, and anterior translation of the humeral head, the undersurface of the posterosuperior aspect of the rotator cuff impinges against the posterosuperior glenoid rim. This is known as internal impingement⁵³ or posterosuperior impingement, but there is considerable debate whether it results from anterior instability or simply an increase in the range of external rotation. A number of potential pathologic sites of pain exist, namely, the rotator cuff, capsule, labrum, glenoid, and greater tuberosity, and differentiation between internal impingement and symptoms of instability can be difficult. It is important to distinguish between internal and subacromial (external) impingement because the etiology, treatment, and rehabilitation differ considerably in the two conditions.

Management of tendinitis in a young patient with instability should be directed at resolution of the symptoms, restoration of normal flexibility and scapular control, correction of faulty technique in athletes, and then strengthening of the dynamic stabilizers of the shoulder joint, notably the rotator cuff muscles. Correction of any muscle imbalance about the shoulder girdle is important (i.e., weakness of the serratus anterior). Arthroscopy has an important role in the treatment of symptomatic instability, even to the extent of carrying out stabilization procedures on the biceps anchor or glenoid labrum, as well as formal reconstruction. In patients with chronic or recurrent instability, surgical stabilization is often required.

PRINCIPLES OF REHABILITATION

Effective rehabilitation of shoulder disorders requires a good understanding of the functional anatomy and biomechanical properties of the shoulder girdle. Pathologies cannot be treated in isolation because of the complex relationship between the cervicothoracic spine, thoracic cage, scapula, and glenohumeral joint. The clinician and physical therapist need to understand this relationship when designing an exercise program for restoring normal

Fig. 73.14 Calcific tendinitis: formative phase (top arrow) and resorptive phase (bottom arrow).

shoulder kinematics. A simple range-of-motion and strengthening exercise program will not suffice, especially for conditions in which scapulothoracic and scapulohumeral rhythm has been disturbed, and in a significant number of patients with shoulder pain it is this scapular dysfunction that has precipitated or aggravated the underlying pathology. Rehabilitation of the

shoulder in an athlete can be complex because the high demands placed on the shoulder lead to muscle fatigue, which in turn can result in a breakdown in shoulder kinematics. Advances in the treatment of shoulder pain in athletes have improved our overall management of shoulder disorders.

The elbow

■ MICHAEL DENIS CHARD ■ KAREN WALKER-BONE

- The elbow is a complex hinge joint that is essential for positioning and full use of the hand.
- Relevant anatomy includes the radiohumeral and ulnohumeral hinge, the connecting proximal radioulnar joint, the radial head, the medial and lateral epicondyles, the ulnar nerve groove, the muscles spanning the elbow, and the olecranon bursa.
- As causes of elbow symptoms, soft tissue lesions such as lateral epicondylitis and olecranon bursitis are far more frequent than joint disease.
- Diagnosis of elbow conditions is largely based on characteristics of the pain, location of the swelling, presence of point tenderness, and the results of passive, active, and resisted motion.

FUNCTIONAL ANATOMY

Bony components

The elbow is accurately classified as a trocho-ginglymus joint because it is a hinged joint that also facilitates rotation (pronation/supination) about a trochlea, or pulley. Flexion and rotation at the elbow bring the hands into view and provide a steady but adjustable base for the hands to maximize use of the highly mobile fingers and opposable thumb. It is a compound synovial joint composed of articulation between the ulnar notch and trochlea of the humerus and between the radial head and humeral capitellum (Fig. 74.1). In continuity with these structures is the proximal radioulnar joint.¹

Humerus

Distally, the humerus expands to form a modified condyle, widest transversely, that consists of articular and nonarticular parts. The capitellum on the lateral aspect is curved, forms less than half a sphere, and contributes anterior and inferior surfaces. A shallow groove separates the capitellum from the medial trochlea, which has anterior, inferior, and posterior surfaces. The medial flange is larger and thus the medial margin projects inferiorly, which results in the plane of the joint being tilted inferomedially. This is the main determinant of the angulation between the long axis of the radius and ulna in an extended supinated position. Medial and lateral bony projections of the lower humerus form the epicondyles, which along with the olecranon, coronoid, and radial fossae, make up the nonarticular part of the condyle. The fossae accept the relevant parts of the ulna and radius during extremes of movement. Above the larger medial and less prominent lateral epicondyle formed by flaring of the distal end of the humerus are the supracondylar ridges. The medial ridge provides a groove for the ulnar nerve as it crosses the elbow and enters the forearm.

Radius and ulna

Proximally, the radius has a head, neck, and tuberosity. The head is discoid, with a shallow cup for the humeral capitellum and an articular periphery that is deepest medially where it contacts the ulnar radial notch. Distal to this is the constriction of the neck, which leads medially to the bony prominence of the tuberosity. The large proximal ulnar segment has large olecranon and coronoid processes, with large trochlear and smaller radial notches to articulate with the humerus and radius. The articulation between the deep trochlear notch and humeral trochlea makes the elbow joint one of

the most congruous and inherently stable. The ulnohumeral and radiohumeral joints provide approximately 50% of the joint's stability, with the rest provided by soft tissues.

Soft tissue components

Ligaments

Varus-valgus stability of the elbow is largely due to the collateral ligaments (Fig. 74.2).² The medial (ulnar) collateral ligament has anterior, posterior, and inferior (oblique) parts. It forms a triangular band with its apex attached around the medial epicondyle and extends in a fan-shaped fashion to insert into a proximal tubercle on the medial coronoid margin (anteriorly) and the medial margin of the olecranon (posteriorly). The anterior portion is the most important elbow stabilizer. The lateral (radial) collateral ligament is attached low on the lateral epicondyle and extends to the annular ligament. Its superficial fibers are blended with those of the attachment of the supinator and extensor carpi radialis brevis.

The strong annular ligament encircles the radial head and holds it against the radial notch of the ulna. It attaches to the edge of the notch anteriorly and on a ridge at or just behind the edge posteriorly. The proximal annular border is continuous with the cubital capsule, except posteriorly, where the capsule passes deep to it at the radial notch. The distal annular border attaches loosely to the radial neck after passing over a synovial reflection. Posterior to the ligament are the anconeus and interosseous recurrent artery. At the point where the ligament is in contact with the radial head internally, it is lined with a thin layer of cartilage, but distally it is covered by a reflected fold of synovium on the radial neck. Recently, mechanoreceptors have been found in the elbow ligaments, thus suggesting that they provide significant sensory function to the elbow joint, as well as being its major mechanical restraints.³

Articular capsule

The elbow has a thin articular capsule. Anteriorly it is broad and attaches proximally to the front of the humerus, medial epicondyle (above the coronoid), and radial fossa (in continuity on its sides with the collateral ligaments), and distally it attaches to the edge of the ulna, coronoid process, and annular ligament. It receives fibers from the brachialis. Posteriorly it attaches to the humerus behind the capitellum, goes around the olecranon fossa (except inferiorly) and the back of the medial epicondyle, and extends to the superior and lateral margins of the olecranon. Laterally it is continuous with the superior radioulnar joint capsule deep to the annular ligament. The anconeus and triceps are related to it posteriorly.

Synovium

The synovial membrane extends from the articular margins of the humerus, lines the articular components of the joint, and descends below the border of the annular ligament. Sometimes the synovial lining of the joint is irregular in the coronoid process on flexion, usually adjacent to the medial collateral ligament, but otherwise it is smooth. Four fat pads are located between the synovium and capsule.

Muscles

The brachialis lies in front of the elbow and triceps with the anconeus behind. The supinator and common extensor tendon of the extensor digitorum communis and extensor digitorum brevis border the joint laterally, and the common flexor tendon and flexor carpi ulnaris border it medially (Fig. 74.3). The biceps tendon passes anterior to brachialis on its way to insertion into the radial tuberosity. The common superficial flexor tendon is attached to the medial epicondyle, and the common superficial extensor tendon is attached to the lateral epicondyle, both outside the joint capsule.

Fig. 74.1 Expanded view of the elbow joint showing the bony features.

Fig. 74.2 Anterior view of the elbow joint showing the ligaments and capsule.

The anconeus attaches to the posterior lateral epicondyle. Above the medial epicondyle on the supracondylar ridge is attached the humeral head of the pronator teres, and the lateral supracondylar ridge provides attachment to the extensor carpi radialis longus. The triceps passes posterior to the elbow joint and inserts into the olecranon.

Bursae

The main bursa around the elbow is the superficial olecranon bursa, which separates the olecranon from the overlying skin. It forms in late childhood.⁴

Movement

Elbow movements arise from the cubital hinge joint, which traverses around 150 degrees, and the proximal radioulnar joint. Pronation (75 to 80 degrees) and supination (85 to 90 degrees) are achievable, provided that both the

Fig. 74.3 Anterior view of the elbow joint showing the muscle insertions.

proximal and distal radioulnar joints are intact.⁵ The shape of the trochlea causes valgus positioning of the forearm in extension (typically 10 to 15 degrees but more in women), or the “carrying angle.” In flexion, the forearm is positioned in varus to facilitate hand-to-mouth movement.

Neurovascular relationships

The arterial supply to the elbow joint comes from numerous periarticular anastomoses supplied mainly by the brachial artery. The articular nerves are derived principally from the radial and musculocutaneous nerves, but the median, ulnar, and sometimes the anterior interosseous nerves contribute. The nerves follow the blood supply and probably contain vasomotor fibers, as well as pain and proprioception afferents. The brachial artery traverses the joint anteriorly, just medial to the biceps tendon in the antecubital space. The musculocutaneous nerve innervates the biceps and the brachialis above the elbow and terminates distally as the lateral cutaneous nerve of the forearm. The median nerve courses anterior to the joint capsule and medial to the biceps tendon and brachial artery. The radial nerve passes anterior to the lateral epicondyle and descends beneath the brachialis and brachioradialis muscles. The ulnar nerve traverses the elbow in the ulnar groove behind the medial epicondyle.

CLINICAL EVALUATION

History

Evaluation of the elbow must be preceded by a precise history to direct the subsequent examination. Symptoms include pain, loss of movement, weakness, clicking, or locking. Pain may be sharply localized, typical of an extraarticular pathologic process, or may be deep or poorly localizable by the patient (typically referred pain). The functional interplay between the elbow, shoulder, and wrist means that examination of all these joints is usually necessary.

Physical examination

Examination must include a comparison of the right and left arms (Table 74.1).

Inspection

Inspection can be very helpful because much of the elbow joint is subcutaneous and alterations in soft tissue or bony anatomy can readily be visualized. The elbow should be viewed in the extended, supinated position from the front to assess the carrying angle, which can be increased in some congenital conditions, such as Turner syndrome, and may be altered by fractures around the elbow. Synovial proliferation and effusion produce fullness around the lateral infracondylar recess, and the swelling caused by an effusion may reduce or fluctuate with the application of pressure. Radial head

TABLE 74.1**Examination of the elbow**

Palpation	Synovium Joint line epicondyles/soft tissues Ulnar nerve
Movement	Active Passive Resisted
Other	Upper limb neurologic examination Neck and shoulder

pathology (e.g., old fracture) may cause hard bony swelling. Posteriorly, swelling of the subcutaneous olecranon bursa may be detected, and in rheumatoid arthritis, nodules often develop and extend distally along the border of the ulna. Occasionally, ulnar neuritis may result in enlargement of the ulnar nerve, which is detected medially.

Palpation

Palpation should include the lateral and medial epicondyles and the olecranon tip. Tenderness over the lateral epicondyle is typical of lateral epicondylitis. The radial head is palpated by applying gentle pressure over the radiocapitellar joint and is assessed during pronation and supination movements. Loose bodies may be detected in the infracondylar recess. Medially, the ulnar nerve may be palpated to detect thickening, and assessment with the elbow in flexion and extension detects ulnar nerve subluxation. The nerve may be displaced anteriorly during flexion, sometimes with an obvious snap, and be associated with ulnar nerve paresthesia. Posteriorly, the tip of the olecranon and the olecranon fossa above can be felt if the elbow is not in full extension. Flexion to around 15 degrees also enables assessment of the collateral ligaments, which may be palpated. Varus stress with the humerus in full internal rotation and valgus stress in full external rotation test for lateral and medial instability, respectively, but abnormality is often subtle and requires experience to detect.

Movement

Movement should be assessed actively and passively, including flexion, extension, and rotation. Most frequently, a reduced range of movement is due to pain. After injury, elbow joint extension is both the first movement to be lost and the last to recover. The full range of normal flexion/extension is greater than that needed for everyday activity, so patients may be unaware of a small fixed flexion deformity. Forcibly moving the joint beyond the pain-free range helps identify the predominant cause of the restriction. In extension, posterior pain indicates a posterior impingement problem, whereas anterior pain is indicative of tightness of the anterior capsule. The reverse is true for loss of flexion. Early in arthritis, flexion and extension are limited, but rotational movements are often spared. Motion is best assessed with the elbow flexed to 90 degrees and held to the side of the body, with supination often being greater than 85 degrees and a little less for pronation.

Pain should be sought on resisted active movements, particularly when there is no major intraarticular pathologic process. These movements are carried out with the elbow held at 90 degrees. Flexion and supination strength is normally greater than extension and pronation. Passive, but not resisted movements producing pain indicate an intraarticular pathologic process, whereas pain on resisted movement alone is indicative of a musculotendinous pathologic process associated with that movement. To complete the assessment, resisted flexion and extension of the wrist must be performed. Elbow assessment is not complete until neurologic examination has been performed, with particular attention paid to structures supplied by the C5, C6, and C7 nerve roots; the biceps jerk (C5), brachioradialis reflex (C6), and triceps jerk (C7) should be assessed as well.

Differential diagnosis of elbow pain

Pain felt at the elbow may be due to either local pathology or referred pain from the neck or shoulder (Table 74.2). In the case of cervical spine lesions, the pain is often associated with frank neurologic symptoms. Although referred pain is usually part of more generalized arm pain symptoms, it may

TABLE 74.2**Differential diagnosis of elbow pain**

Local	
Articular	Arthritis, osteochondritis, loose bodies, subluxation
Periarticular	Lateral and medial epicondylitis, olecranon bursitis, ligamentous lesions, entrapment neuropathy
Referred	Cervical and shoulder disease

be localized. Examination of the neck and shoulder is therefore important when assessing elbow pain. Intrathoracic pathologic processes can give rise to arm pain but are rarely localized to the elbow.

True elbow pain may be related to joint disease (osteoarthritis, rheumatoid arthritis, gout) but is more commonly due to lesions of the soft periarticular tissues. These causes can usually be distinguished by the history and appropriate examination. Traumatic effusions can occur and the joint may be involved by a fracture of the bones, with minor fractures sometimes being missed until an effusion develops. A traumatic/overuse form of osteochondritis of the radial head can occur in some throwing sports, especially in adolescents. The joint may be affected by loose bodies and synovial osteochondromatosis. Traumatic partial subluxation of the radial head through the annular ligament occurs in children, particularly those with hypermobility.

Investigations

Plain anteroposterior and lateral radiographs are useful in assessing bone and joint pathologic processes. Further investigation by arthroscopy⁶ is very useful, but magnetic resonance imaging (MRI) is often a preferable, noninvasive alternative. MRI and MR arthrography are better than computed tomographic arthrography, although the latter technique is better for assessing the cartilage of the elbow.⁷ High-resolution ultrasonography is a less costly alternative and is particularly useful for assessment of periarticular soft tissues,⁸ especially with the development of color (power) Doppler imaging, which allows detection of abnormalities in blood flow and new vessel formation (angiogenesis), in addition to standard gray-scale ultrasonography. Ultrasonography is very dependent on operator skill, although the precision of the latest equipment is enabling some clinicians to use it as an office investigation.

SOFT TISSUE ELBOW LESIONS

The principal soft tissue lesions of the elbow are lateral epicondylitis (“tennis elbow”), medial epicondylitis (“golfer’s elbow”), and olecranon bursitis. Both epicondylar and radioulnar bursitis have been reported but are rare and produce vague symptoms around the elbow and swelling.

Olecranon bursitis

The principal bursitis at the elbow is olecranon bursitis. The condition is most commonly seen in younger men and is often related to recurrent elbow trauma sustained either at work (e.g., automobile mechanics, miners) or during leisure activities (throwing darts, gymnastics, gardening). Frequently, no obvious precipitating cause of olecranon bursitis is found. It occurs rarely in childhood for developmental reasons.⁴

Etiology

The olecranon bursa is a subcutaneous synovial pouch located on the extensor aspect of the elbow. Because of its superficial position with little soft tissue padding, it is vulnerable to trauma by friction or a blow and to infection through abrasions, puncture wounds, or cellulitis. Olecranon bursitis occurs when the bursa swells because of trauma, inflammation, or infection (Fig. 74.4). Such swelling occurs easily and is readily visible. The swelling may be the result of fluid accumulation but may also be due to synovial tissue hypertrophy or fibrosis. In addition to trauma, the bursa may be involved in crystal arthropathies (gout or, rarely, calcium pyrophosphate arthritis) or in generalized inflammatory arthritis, especially rheumatoid arthritis. Swelling of the olecranon bursa may be seen in association with rheumatoid nodules on the ulnar border of the forearm (Fig. 74.5). Rheumatoid nodules may form within the bursa, but intrabursal nodules may also form as a consequence of traumatic fibrosis or gouty tophi.

Clinical aspects

Olecranon bursitis can be classified clinically into three general categories (Table 74.3):

- Traumatic (or idiopathic) noninflammatory
- Aseptic inflammatory
- Septic inflammatory

Appropriate therapy depends on the category, which must be determined quickly via the history, examination, and when appropriate, bursal aspiration. The main diagnostic challenge is to distinguish septic from nonseptic inflammatory bursitis because septic bursitis has the greatest potential for morbidity. Clinicians must also be aware of the potential for rapid change in the nature of the bursitis, that is, a change from nonseptic to septic. This possibility should be considered at each follow-up visit.

Specific enquiry about occupation, duration of symptoms, and possible trauma or skin injury is important. Information on other causes of bursitis, such as rheumatoid arthritis, gout, or uremia, should be sought. Diabetes or conditions associated with immunosuppression can increase the risk for sepsis. During physical examination the size and turgor of the bursa should be noted (as well as change in size at follow-up visits). Warmth and

erythema of the bursa or skin along with the presence of nodules or lymphadenopathy provide important clues. An effusion in the adjacent elbow joint may occur, especially with inflammatory arthritis. Evidence of trauma, particularly with skin breakage, should be sought. General physical status should be assessed, especially the presence of fever. Key features in the differential diagnosis are provided in Table 74.3.

With traumatic or idiopathic olecranon bursitis, the pain is usually localized and typically does not occur on passive or resisted movement. It is generally provoked by leaning on the elbow or flexion with a constriction around the elbow such as a coat sleeve. Tenderness should be sought about the tip of the olecranon and will be present, sometimes with palpable thickening of the bursal wall, even in the absence of significant effusion; the area is usually very sensitive to pressure. Septic olecranon bursitis occurs less frequently but should not be missed. In general, it occurs after an abrasion or may be associated with an initial cellulitis of the skin. Septic olecranon bursitis can be differentiated from acute arthritis by gentle passive extension, which is unimpaired.⁹

When inflammation or infection is suspected, percutaneous diagnostic aspiration of the bursa is indicated. Aspiration both reduces symptoms and allows assessment of the fluid. Along with gross visualization of blood staining or turbidity of the fluid, a white cell count and differential and Gram

stain with culture of the fluid should be undertaken to exclude infection. Polarized light microscopy should be performed for detection of crystals. Elbow radiographs are rarely necessary and should be obtained only to exclude traumatic fracture or preexisting joint injury. Ultrasonography can be used to define the characteristics of the bursitis and may assist in needle placement for aspiration and injection in some cases. MRI provides even greater soft tissue definition but cannot reliably distinguish septic from nonseptic bursitis.

Management

Noninflammatory, traumatic (or idiopathic) bursitis usually responds to simple conservative therapy, including rest, elbow protection, and treatment with antiinflammatory drugs. Padded elbow support may help prevent further trauma and skin abrasion. Percutaneous needle aspiration should be considered in patients with significant symptoms. The aspiration itself reduces symptoms, and in addition, a compressive elastic bandage may be used to prevent recurrence of swelling. If infection has been excluded satisfactorily by culture, local corticosteroid injection may be performed, which is effective in speeding recovery.¹⁰ However, it can lead to complications (infection, skin atrophy, chronic pain) and should be used only sparingly for traumatic bursitis. In inflammatory olecranon bursitis related to rheumatoid arthritis or crystalline arthropathy, intrabursal corticosteroid injection is useful. In such cases it should be preceded by aspiration and investigation to exclude infection. An injection of 20 mg methylprednisolone acetate generally leads to rapid recovery.

The finding of infection requires appropriate antibiotic therapy and repeated aspiration as necessary. *Staphylococcus aureus* is the most frequent organism, with group A α -hemolytic streptococci and *Streptococcus epidermidis* being found less commonly.^{9,11} Rarely, *Haemophilus influenzae* and *Pseudomonas* species may be the cause. In immunocompromised patients (malignancy, human immunodeficiency virus [HIV]-positive status, or systemic corticosteroid therapy), specific cultures for atypical organisms, including mycobacteria, fungi, or anaerobic bacteria, should be considered.

Patients who fail to respond to outpatient therapy or who have more severe infection at the outset need to be hospitalized for intravenous antibiotic therapy. This category includes patients with high fever, chills, prolonged duration of symptoms, and cellulitis. Hospitalization also needs to be considered for those with complicating medical conditions (diabetes, uremia, rheumatoid arthritis) and immunosuppression.

Repeated aspiration of the infected bursa is essential and may initially need to be carried out on a daily basis. It can be done percutaneously or, if necessary, with placement of a suction-irrigation system. Cell counts and repeated culture should be performed to monitor response to therapy. Patients initially requiring intravenous antibiotic therapy can be switched to oral medication as soon as the signs and symptoms show consistent improvement. In general, antibiotic therapy should be continued for 10 to 14 days, although some evidence indicates that patients commencing treatment within a week of onset actually require only half this duration to sterilize the bursa.

Surgical drainage or bursectomy is occasionally needed for the management of olecranon bursitis. If repeated traumatic bursitis occurs, surgical removal of the bursa should be considered, either arthroscopically or by open resection. Persistent aseptic inflammatory bursitis may necessitate open resection. Bursectomy may be required for septic bursitis if the acute infection fails to resolve or if after repeated infection a fibrotic, chronically inflamed bursa is left.¹²

Lateral epicondylitis

Epidemiology

Used synonymously with the term *tennis elbow*, this condition is one of the most common specific upper limb disorders. The first description is attributed to Runge in 1873,¹³ but the name “tennis elbow” is derived from Morris’s description of “lawn tennis arm” in *The Lancet* in 1882.¹⁴ Prevalence rates of 0.7% to 2.5%^{15,16} have been reported, with higher rates in manual workers, particularly those performing repetitive bending and straightening of the elbow.¹⁷ Racket sports may be a risk factor, but this has been poorly evaluated, and less than 5% of cases in clinical practice are due to such sports.¹⁸ Nonetheless, the majority of cases do not occur in manual workers, and many cannot describe any specific precipitating factors.¹⁹ Symptoms may be brought on by overuse, and hence lateral epicondylitis is more often seen in the active middle-aged population than in the less active elderly population. In manual workers, relative overuse of the wrist and finger extensors may precipitate or exacerbate the condition, and the dominant arm is most often affected. Sometimes there may be bilateral involvement,

Fig. 74.6 Angiofibroblastic hyperplasia.

either as a result of increased stress placed on the unaffected arm or from a general tendency of some individuals to incur soft tissue lesions.^{17,19}

Etiopathology

More than 25 causes of the condition have been suggested,¹⁹ and this reflects use of the diagnosis nonspecifically for lateral elbow pain. Pathologic material for study is relatively rare because most cases do not come to surgery. Reported operative findings in relatively few chronic cases have included periostitis,¹³ infection,²⁰ radiohumeral joint disease,²¹ radial nerve entrapment,²² and a lesion of the orbicular (annular) ligament.²³ It is thought, however, that the majority of cases are due to a musculotendinous lesion of the common extensor tendon at the attachment to the lateral epicondyle or nearby, especially the portion derived from the extensor carpi radialis brevis.¹⁷ The anatomic location of the extensor carpi radialis brevis makes the undersurface vulnerable to contact and abrasion against the lateral edge of the capitulum with the elbow in motion.²⁴

Originally thought to be an inflammatory lesion, no histologic evidence of inflammation has been found in biopsy material. The reported changes found are consistent with degeneration and attempted repair. Such changes include cystic and fibrinoid degeneration, round cell infiltration, immature fibrous tissue, hyaline degeneration, and vascular plus fibroblastic proliferation (“angiofibroblastic tendinosis”; Fig 74.6), sometimes with calcific debris.^{16,17,25,26} Some cases show a chronic traction effect. The angiogenesis as part of the process is consistent with the vascular changes seen on color (power) Doppler imaging.^{8,27} The changes reported are similar to those seen in the rotator cuff with advancing age, in which tendon vascular factors are thought to be important.²⁸ Some evidence indicates that neurogenic changes of the enthesis may be part of the pathophysiology.²⁹ Ischemic stress may be part of the mechanism because the tenoperiosteal junction (enthesis) and nearby tendon are relatively avascular (the blood supply is a watershed of that derived from muscle and bone) and working muscle takes up the blood supply at the expense of tendon. Lateral epicondylitis is rare in those younger than 30 years, suggesting that aging effects are important and alterations occur in the enthesis in adulthood, including changes in collagen content, reduction in cells and ground substance, and an increase in lipids, which may predispose to injury.³⁰ Other possible factors, including tendon elasticity, have yet to be elucidated. Basic science biochemical investigation of tendon turnover in relation to age and disease may, in the future, lead to further insight into the pathophysiology and possibly novel therapies.

Clinical findings

Lateral epicondylitis usually arises slowly and seemingly spontaneously, with few patients recalling a blow or acute traumatic strain. Pain localizes to the lateral epicondyle but may spread proximally or distally. Grip is impaired because of pain, which may result in restricted daily activities. Tenderness over the epicondyle is usual, although maximum tenderness is sometimes found nearby.²³ The other cardinal sign is an increase in pain on resisting wrist dorsiflexion with the elbow in extension (Fig. 74.7). Symptoms may also be precipitated by extending the elbow with the wrist flexed (Fig. 74.8) and by resisted middle finger extension. Resisted supination may also be painful. Range of movement of the elbow is generally normal, but a few degrees of extension may be lost in severe or chronic cases.

Differential diagnosis

It is important to exclude other conditions producing elbow pain, especially that referred from the cervical spine or shoulder or arthritis of the elbow.

Fig. 74.7 Resisted wrist extension test.

Fig. 74.8 Forced elbow extension test.

Nerve entrapment around the elbow may produce diagnostic confusion. Radial tunnel syndrome or compression of the posterior interosseous nerve²² can provoke lateral elbow and upper forearm pain. It can be the cause of apparent lateral epicondylitis that is unresponsive to conservative treatment but is thought to be a rare cause of resistant cases. These entrapments have been found to be due to compressive lesions caused by abnormal fibrous bands in front of the radial head, a sharp tendinous origin of the extensor carpi radialis brevis, or a radial recurrent fan of vessels. More rarely, a lipoma or ganglion has been found. Compression of the posterior interosseous nerve may occur at the point where it passes through the supinator muscle just below the elbow joint. A well-defined arcade of Fröhse is present in 30% of subjects³¹ and makes a compression neuropathy more likely. Diffuse pain, symptoms distal to the lateral epicondyle, and the presence of muscle weakness may be useful distinguishing features.

Investigations

Investigations are not usually required, but radiographs of the elbow may be helpful in excluding joint disease and may show lateral soft tissue calcification. Electromyography may be helpful in excluding nerve entrapment. Quantitative assessment of severity and response to treatment is difficult, but grading pain, tenderness, and pain on resisted wrist extension can be helpful, and lifting graded weights and grip strength measurement aid objectivity.³² A truly objective measure is infrared thermography of the affected elbow, which shows a discrete localized area of increased heat near the lateral epicondyle in 98% of affected elbows (Fig. 74.9). Analysis of the gradient across the abnormal area reveals a correlation with clinical severity. Lack of general availability of this technique has restricted its use to research. MRI can be used to identify tissue abnormalities before surgery in resistant cases, but the changes identified do not positively correlate with

Fig. 74.9 Lateral epicondylitis. Infrared thermography in a patient with lateral epicondylitis shows a localized "hot spot"

TABLE 74.4

NSAID, nonsteroidal antiinflammatory drug.

symptoms.³³ High-resolution ultrasonography, especially with color (power) Doppler, is being used increasingly to assess the tissue lesion at an earlier stage and can be of assistance in guiding treatment, including therapeutic injections, and assessing response. In the future the technique may help in predicting resistant cases that will require surgical intervention.^{8,27}

Management

More than 40 treatment regimens for lateral epicondylitis ranging from extremes of "prolonged observation" to x-ray therapy have been described in the literature. Reduced activity may relieve the symptoms in some cases, especially early and in conjunction with splinting (Table 74.4). Though used widely, a systematic review of orthotic devices found that no definite conclusion could be drawn on their effectiveness.³⁴ Oral nonsteroidal antiinflammatory drugs (NSAIDs) or NSAID gels are often used. They have some benefit but have been evaluated only in the short term.³⁵

Numerous physical modalities of treatment of lateral epicondylitis have been tried, but the efficacy of most remains unproven. Lack of evidence may relate to the lack of high-quality trials rather than lack of efficacy. Studies of ultrasound therapy have yielded conflicting results.³⁶ Benefit has not been shown for low-level laser light therapy, possibly because optimal doses and wavelengths were not used.³⁷ Extracorporeal shock wave therapy (lithotripsy) has been suggested for persistent cases, but its efficacy has not been confirmed by controlled studies.³⁸ The reason for this, despite its benefit in some other tendinopathies, is uncertain but may relate to the relative rarity of tendon calcification in this type of tendinopathy. Acupuncture has also been used for treatment but has thus far been shown to have only short-term benefit.³⁹ Evidence accumulated in recent years has suggested that the best physical modality of treatment is an eccentric exercise program.⁴⁰ Various forms have been advocated, either using apparatus or in the form of a simple home exercise program.

Local injections of corticosteroids have been used widely for many years. They produce a rapid response in up to 90% of subjects, albeit often with transient increased pain. Good benefit is achieved for 6 weeks, but as a consequence of a significant relapse rate, long-term benefit is often no better than that with noninvasive approaches to management.^{41,42} Whether this is true failure of the corticosteroid or rapid improvement in pain leading to increased activity too soon is unknown. Some evidence suggests that those

who relapse have a worse long-term prognosis than when just a wait-and-see modified approach is used.^{36,41} These factors, coupled with mounting evidence that the pathology is not inflammatory, have led to increasing consensus that local corticosteroid injections should generally be avoided and that they should be used mainly when a rapid response is important, such as job retention, and then only after suitable counseling about the risks and benefits.

In recent years a number of other treatment modalities have been proposed. Topical nitric oxide delivered via a glyceryl trinitrate patch appears to be beneficial but it has to be applied daily for up to 6 months, and vasodilatation side effects (headache and dizziness/hypotension) can be a problem.⁴³ Autologous platelet-rich plasma injections have been used, but in its 2009 review of this procedure, the National Institute for Health and Clinical Excellence concluded that the evidence available was inadequate for the procedure to be recommended.⁴⁴ Since then, a recent high-quality randomized controlled trial has shown superior long-term benefit over local corticosteroid injections after 2 years of follow-up,⁴⁵ but it is currently unclear whether this technique is better than conservative management, and it is expensive. Similar concerns exist with regard to other treatments, including dry needling, prolotherapy, and injection of autologous blood stem cells or autologous tenocytes. In addition, there is uncertainty about the added value of guiding such injections to the injured tendon tissues with ultrasonography.

Botulinum toxin A injection into the origin of the extensor forearm muscles to temporarily partially paralyze the muscles, particularly the extensor digitorum longus, has been used with the aim of interrupting the repetitive microtrauma, albeit at the expense of some weakness. However, the results have been conflicting. A recent randomized placebo-controlled trial of periarticular hyaluronate gel injection, more commonly used intraarticularly for osteoarthritis, has shown benefit.⁴⁶ Preliminary study of injection of the matrix metalloproteinase inhibitor aprotinin to treat tendinopathy at other anatomic sites has shown some promise but has yet to be used for lateral epicondylitis.⁴⁷

One difficulty with assessment of treatments is that the natural history of lateral epicondylitis is thought to be resolution in around 80% of cases after about 1 year. Treatments are aiming at achieving recovery sooner, but there is concern that failure of some treatments or relapse after improvement may adversely affect outcomes and be worse than a wait-and-see approach.⁴¹ Up to 20% of patients are resistant to conservative management, but we cannot currently reliably identify these patients in the early stages.

Role of surgery

Surgery is usually offered for the approximately 10% of patients failing to respond to conservative measures and should be suggested only after at least 12 months of conservative treatment. The value of manipulation as a means of avoiding surgery is controversial. No evidence-based consensus has been reached on the best surgical management.⁴⁸ Although elbow arthroscopy is becoming more widespread, most published data relate to open procedures involving either resection or débridement of damaged tissue and tendon repair, with or without decortication or drilling of the lateral epicondyle.^{17,25} Alternatively, surgery can involve “lateral release” by division of the origin of the common extensor tendon. Proponents of both approaches claim benefit in up to 90% of cases. The latter approach may be more cost-effective because it can be carried out as a simple percutaneous procedure with a local anesthetic and thus may be done as ambulatory surgery or even as an office procedure.^{48,49} A randomized controlled study comparing standard open débridement and repair surgery with percutaneous “lateral release” reported that recovery and return to work were significantly quicker after the simpler technique.⁵⁰ Arthroscopic release, though more technically challenging and time-consuming, has been shown in a comparative study to be as good as the standard open technique, but with quicker return to work.⁵¹ Also, advocates of arthroscopy point to the fact that the joint can be examined at the same time and may reveal abnormalities contributing to the symptoms and allow their correction. It is generally agreed that extensive lateral release plus resection of the proximal third of the annular ligament is best avoided because of the risk for subsequent elbow instability.

Fig. 74.10 Resisted wrist flexion test.

Prognosis

Lateral epicondylitis is said to improve with time, along with modification of activities. Minor discomfort may persist for several years, and manual workers are at particular risk for recurrence on resumption of the activity that initially induced the pain.¹⁹ Treatment is aimed mainly at settling the condition more quickly, but risk versus benefit, along with cost, has to be considered carefully. Most treatments described for lateral epicondylitis, conservative or operative, are not supported by robust scientific evidence. Until greater proof is available, clinicians need to be guided by the existing evidence, a pragmatic, if subjective viewpoint, and clinical experience.

Medial epicondylitis

Otherwise known as “golfer’s elbow,” this condition is less common than lateral epicondylitis, with a prevalence estimated to be 0.6% in men and 1.1% in women and a peak in middle age.¹⁶ It is a lesion of the common flexor tendon at the medial epicondyle. As with “tennis elbow,” a sporting cause is relatively rare. The condition may cause pain and tenderness slightly less well localized to the medial epicondyle, often felt a little distal to the flexor origin. Pain on resisted wrist flexion with the elbow in extension is the most reliable sign (Fig. 74.10), although rarely, flexion of the fingers rather than the wrist best elicits symptoms. The pathology and management are essentially the same as for lateral epicondylitis, but few data are available on response to treatment of medial epicondylitis.

Other disorders of the elbow

Biceps tendinitis is characterized by local pain and tenderness in the region of the bicipital tuberosity of the radius together with pain on resisted flexion and supination. Pain on resisted flexion alone indicates the rarer brachialis muscle lesion, a condition associated with pain and tenderness that is less well localized and found behind the biceps tendon. Though uncommon, such a tear is particularly prone to the development of myositis ossificans, which in the early phases produces a warm, firm mass that can be mistaken for a tumor. Pain on resisted supination alone is said to indicate a supinator lesion, but this very rarely, if ever occurs and pain would be felt farther down the forearm. It is unusual to have a lesion at the site of the triceps insertion into the olecranon (triceps tendinitis); instead, these lesions occur higher in the arm at the musculotendinous junction. Ligamentous lesions do not usually occur in isolation and are most often associated with traumatic joint synovitis or effusion, if not frank joint derangement or fracture. Medially, a ligamentous lesion may form at least part of the elbow injury caused by some throwing sports, such as javelin, and may, if an overuse injury, need to be distinguished from medial epicondylitis.

The wrist and hand

■ GEORGE S.M. DYER ■ BARRY P. SIMMONS

- Pain or loss of function in the wrist and hand may originate in the bones and joints, periarticular soft tissues, or peripheral neurovascular structures or may be referred from the cervical spine, thoracic outlet, shoulder, or elbow.
- Precise diagnosis depends on a meticulous history, a thorough physical examination, and appropriately selected diagnostic studies.

INTRODUCTION

The hand is the main tactile sensory organ and is uniquely designed for fine motor activities. Any deviation from the normal architecture or limitation from a painful condition may lead to disability. Understanding this anatomy in detail will help in diagnosis and treatment (Figs. 75.1 to 75.4).¹⁻⁷ The focus of this chapter is on common localized disorders of the hand and wrist.

CLINICAL EVALUATION

History

The evaluation should begin with a complete history—the start of symptoms; their location, nature, and duration; and factors that aggravate or alleviate them. Frequently, chronic conditions have simply worsened over time, and the patient may relate a history of repetitive or strenuous activity that has become more painful or difficult.

Physical examination

The examination should include observation of resting posture and inspection for the presence of any swelling, deformity, ecchymosis, atrophy, or skin and nail changes.^{2,5,6} Understanding the surface anatomy of the hand and wrist is important in evaluating injuries (Fig. 75.5).

Resting posture

At normal rest the metacarpophalangeal (MCP) joints are flexed 45 to 70 degrees, and each of the interphalangeal (IP) joints are slightly flexed up to 10 degrees.⁸ Rheumatoid arthritis (RA) and other chronic inflammatory diseases can cause volar subluxation of the carpus, carpal collapse, and radial deviation of the carpus. Chronic arthritis of the distal radioulnar joint may result in instability with dorsal subluxation of the ulnar head, which displays a “piano key” movement on downward pressure.⁴

Swelling and deformity

The fingers and thumb may demonstrate swelling and deformity of the joints, clubbing, subcutaneous nodules, gouty tophi, Heberden (distal IP [DIP] joint) or Bouchard (proximal IP [PIP] joint) nodes, sclerodactyly, telangiectasia, ischemic digital ulcers, pitting of the skin, nail fold abnormalities, periungual erythema, or psoriatic skin and nail lesions.^{4,5} Swelling secondary to MCP synovitis may obliterate the normal concavity seen between the metacarpal heads. Digital flexor tenosynovitis produces diffuse swelling (sausage finger) with tenderness over the volar aspect of the finger along the tendon sheath. MCP joint deformities include ulnar drift, volar subluxation, and flexion deformities. RA is a disease that affects the soft tissues (ligaments and tendons) of the hand as much as the bones. As a

category, these deformities all arise from alterations in the delicate balance between extensors and flexors acting on the phalanges. A boutonnière deformity is flexion of the PIP joint and hyperextension of the DIP joint (Fig. 75.6a). A swan neck deformity describes hyperextension of the PIP joint and flexion of the DIP joint (see Fig. 75.6b). A Z-shaped deformity of the thumb (commonly seen in RA) involves flexion of the MCP joint and hyperextension of the IP joint (see Fig. 75.6c).⁴ Telescoped shortening of the digits, produced by partial resorption of the phalanges with loss of the articulations secondary to psoriatic arthritis, RA (arthritis mutilans), or inflammatory arthritic conditions, may demonstrate concentric wrinkling of the skin (opera-glass hand).⁴

Differential diagnosis of joint swelling

It is important to distinguish between joint effusion and tenosynovial inflammation from a localized mass. Patients with tenosynovitis have more passive than active range of motion. Arthritis of a joint generally produces a diffuse circumferential swelling, whereas extensor tenosynovitis is usually characterized by a longitudinal or oval dorsal swelling localized to the region of the tendon sheath at the wrist level. When the fingers are actively extended, the distal margin of the swelling moves proximally and folds in, like a sheet being tucked under a mattress (“tuck” sign).^{2,4} Tenosynovitis of the common flexor tendons will be manifested as swelling on the volar aspect of the wrist just proximal to the carpal tunnel (volar “hot dog” sign).⁴ The wrist is also a relatively common site for benign masses; ganglions may mimic the just-mentioned inflammatory processes (Fig. 75.7).

General examination

Dryness or cracking of the fingertips can indicate nerve injury. Normal capillary refill takes less than 2 seconds. The Allen test evaluates the vascular arches of the hand. Sensory function of the fingertips is evaluated by light touch and two-point discrimination with a custom-bent paper clip or calipers. Normal two-point discrimination is less than 5 mm.⁹

Palpation can often localize a specific region with an underlying pathologic process. The wrist is best examined in slight flexion by palpating the dorsal surface of the wrist with the thumbs while supporting the wrist with the fingers of both hands.^{2,3} This technique can gently identify and often distinguish an effusion, inflamed tenosynovium, or another dorsal wrist pathologic process. A similar technique is suited to the carpometacarpal (CMC) and MCP joints as well, where thick volar skin, subcutaneous tissue, and flexor tendons may make volar palpation less helpful. Dorsal fluctuance may indicate an effusion: pressure from one hand on one side of the joint will produce a fluid wave that will be transmitted to the second hand placed on the opposite side of the joint.⁴

The PIP and DIP joints are palpated for nodules, tenderness, capsular irregularities, or effusion by placing the thumbs and forefingers of both hands on opposite sides of the joint.³ Although synovitis and other inflammatory processes may cause tenderness, the dorsal knuckle pads demonstrate nontender, thickened skin localized to the dorsal surface of the PIP joints.⁴

Tendon nodules usually occur at the level of the metacarpal heads opposite the A1 pulleys, just proximal to the MCP flexion creases in the palm. These nodules can be palpated in the palm while the patient slowly flexes and extends the affected finger, which may result in a “triggering” sensation.

Range of motion

Active motion should be assessed before passive manipulation. Lack of ability to flex or extend across a joint or malalignment with motion may indicate either underlying tendon disruption or displacement or joint subluxation or dislocation. As the digits are flexed, the fingertips should point

BONES AND JOINTS OF THE WRIST AND HAND

Fig. 75.1 Bones of the wrist and hand. (Used with permission from Fam AG. *The wrist and hand*. In: Hochberg M, Silman A, Smolen JS, et al, editors. *Rheumatology*. 3rd ed. St. Louis: Mosby; 2003, p. 641-50.)

toward the scaphoid. The distal nail tips should be rotationally aligned when the fingers are in a partially flexed position.

Wrist motion should be assessed for flexion, extension, pronation, supination, and radial and ulnar deviation. The normal range is 65 to 80 degrees of flexion, 55 to 75 degrees of extension, 30 to 45 degrees of ulnar deviation, and 15 to 25 degrees of radial deviation.¹⁰ The intercarpal joints and radiocarpal joint allow wrist flexion and extension. Pronation and supination of the hand and forearm occur at the proximal and distal radioulnar joints. Full composite digital flexion should allow the fingertips to touch the palm opposite the MCP joints at the level of the distal palmar crease (see Fig. 75.5). Motion at the thumb CMC joint is variable within the population. The sum of thumb CMC, MCP, and IP motion is about 180 degrees in most healthy people, but the proportion of motion at each joint is distributed differently such that some people have stiffer CMC joints but looser MCP and IP joints or vice versa. Disease may change these proportions. Patients with arthritis of the thumb CMC joint may compensate for lost CMC motion by hyperextending the thumb MCP joint to preserve the span of the first web space for encompassing large objects.

Strength testing should include resisted motion across each joint. Resisted DIP flexion will test the strength of the flexor digitorum profundus, and testing individual digits for resisted PIP flexion while maintaining the other digits extended will evaluate function of the flexor digitorum superficialis. Isolated extension across the MCP, PIP, and DIP joints is important in patients with rheumatic disease to separate extrinsic and intrinsic extensor capabilities.

Stability of the MCP joint is evaluated by flexing it to 90 degrees to place the radial and ulnar collateral ligaments on stretch and then attempting lateral motion while stabilizing the metacarpal joint. The stability of the radial and ulnar collateral ligaments of the PIP and DIP joints can be assessed by applying lateral stress with the joint at 0 and 30 degrees of flexion.

FLEXOR TENDON SHEATHS OF THE WRIST AND FINGERS

Differential diagnosis of wrist and hand pain

Pain and functional disability in the wrist and hand are common symptoms that can be caused by a wide range of underlying conditions, including pathologic processes of the bones and joints of the wrist and hand, periarticular soft tissues, tendons, and peripheral neurovascular structures, or may be referred from the more proximal structures of the cervical spine, thoracic outlet, shoulder, or elbow. Table 75.1 details many disorders of the wrist and hand based on the site of origin of symptoms and the primary location. Precise diagnosis rests on a thorough history and physical examination and a few rationally selected diagnostic studies.

SPECIFIC DISORDERS OF THE WRIST AND HAND

Tenosynovitis

As the extrinsic tendons cross the wrist, they provide both power and dexterity to the hand. Each tendon passes through a tendon sheath, which is lined by an inner (visceral) synovial layer that adheres closely to the tendon and an outer (parietal) synovium that covers the inside of the fibrous tendon sheath.⁴ The visceral and parietal synovial sheaths are attached by the

Fig. 75.6 Deformities of the fingers and thumb. (a) Boutonnière deformity. (b) Swan neck deformity. (c) Z-shaped deformity of the thumb. (Used with permission from Fam AG. *The wrist and hand*. Fig. 75.7 Dorsal wrist ganglion.

mesotendon, through which pass vessels and nerves to the tendon. The mesotendon may be less substantial in some tendon sheaths and be represented only by threads or vinculae.¹¹ With aging, tendons become less elastic and less able to tolerate stress without injury.⁴

Stenosing tenosynovitis is usually an idiopathic condition that results from inflammatory changes, including fibrosis and thickening of the tendon sheath and “fibrillar creep” of the tendon in which the fibers become edematous and bunched.^{11,12} The result is that tendon gliding is impaired and the patient may experience “catching,” “triggering,” or “locking” on either side of the retinacular ligament or pulley. Tenosynovitis is uncommonly related to a single traumatic event.

Patients with tenosynovitis most frequently describe symptoms of discomfort along the tendon, stiffness or lack of motion of the digit, and swelling. On examination, tenderness will be present along the affected tendon longitudinally and crepitus may be palpated, especially with motion. Provocative testing includes placing the tendon under tension, either by resisted muscular contraction or by passive stretching, which will result in an exacerbation of the symptoms.

de Quervain tenosynovitis, intersection syndrome, and trigger finger/thumb are all common conditions caused by “primary” tenosynovitis unrelated to an underlying medical condition.

Secondary causes of tenosynovitis are less common and include RA, systemic lupus erythematosus, scleroderma, psoriatic arthritis, reactive arthritis, infection (bacterial, mycobacterial, fungal, and viral), microcrystalline disease (gout and calcium pyrophosphate and hydroxyapatite or calcific tenosynovitis), amyloid deposition, sarcoidosis, and pigmented villonodular tenosynovitis.⁴

de Quervain syndrome

de Quervain syndrome describes tenosynovitis of the first dorsal compartment tendons: the abductor pollicis longus (APL) and the extensor pollicis brevis (EPB) (see Fig. 75.4). It is most common in women between 30 and 50 years of age^{4,11,13,14} and may occur in association with rheumatoid, psoriatic, or other inflammatory arthritis conditions, localized trauma, and pregnancy or during the postpartum period.^{15,16} Repetitive activity that involves active thumb flexion while radially and ulnarly deviating the wrist may result in inflammation and subsequent thickening and stenosis of the tendon sheath as it passes over the radial styloid beneath the extensor retinaculum.¹⁷ This may lead to significant radial-sided wrist pain with focal swelling and tenderness and crepitus 1 to 2 cm proximal to the radial styloid over these tendons (Fig. 75.8).¹³ In the Finklestein test the thumb is flexed into the palm and then the wrist is gently ulnarly deviated to reproduce the focal discomfort.¹⁸

Symptoms of de Quervain tenosynovitis may be similar to those of osteoarthritis of the first CMC joint or intersection syndrome.

Patients with mild symptoms may be treated by activity modification, rest, use of a long opponens splint with the IP joint free, and antiinflammatory medication.¹⁹ With more severe or persistent pain, corticosteroid injection may be beneficial and can result in complete and lasting relief in about 70% of patients.²⁰⁻²² If conservative management fails to alleviate the symptoms, surgical release of the first dorsal compartment may be appropriate.²¹ Up to 76% of patients have more than one slip of the APL tendon and 60% have a dividing septum in the compartment, which should be released if identified at surgery.²³

Intersection syndrome

Intersection syndrome occurs at the “intersection” where the APL and EPB cross over the extensor carpi radialis longus and brevis approximately 4 cm proximal to the wrist joint.^{24,25} It results from the frequent repetitive wrist

TABLE 75.1

Differential diagnosis of wrist and hand pain

Articular	
Arthritis of the wrist, MCP, PIP, and/or DIP as a result of	Trauma, hypermobility, sprain RA (wrist, MCP, PIP joints) Osteoarthritis (first CMC, PIP, and DIP joints) Other forms of arthritis: gout, psoriatic arthritis, infection Joint neoplasm
Periarticular	
Subcutaneous	RA nodules, gouty tophi, painful subcutaneous calcific nodules in scleroderma, glomus tumor of the nail bed
Palmar fascia	Dupuytren contracture
Tendon sheath	Wrist extensor tenosynovitis, including de Quervain tenosynovitis and extensor carpi radialis tenosynovitis Wrist volar flexor tenosynovitis (including carpal tunnel syndrome) Thumb flexor tenosynovitis (trigger or snapping thumb) Finger flexor tenosynovitis (trigger finger) Pigmented villonodular tenosynovitis (giant cell tumor of the tendon sheath)
Acute calcific periarthritis	Wrist, MCP, and rarely the PIP and DIP joints
Ganglion	
Osseous	
Bone lesions	Fractures, neoplasm, infection, osteonecrosis, including Kienböck disease (lunate) and Preiser disease (scaphoid)
Neurologic	
Nerve entrapment syndromes	
Median nerve	Carpal tunnel syndrome (at the wrist) Pronator teres syndrome (at the pronator teres) Anterior interosseous nerve syndrome
Ulnar nerve	Cubital tunnel syndrome (at the elbow) Guyon canal (at the wrist)
Posterior interosseous nerve syndrome	Radial nerve palsy (spiral groove syndrome)
Lower brachial plexus	Thoracic outlet syndrome, Pancoast tumor
Cervical nerve roots	Herniated cervical disk, tumors
Spinal cord lesion	
Spinal tumors, syringomyelia	
Vascular	
Vasoplastic disorders with Raynaud phenomenon	Scleroderma, occupational vibration syndrome, etc.

Fig. 75.8 de Quervain tenosynovitis of the wrist. (Used with permission from Fam AG. *The wrist and hand*. In: Hochberg M, Silman A, Smolen JS, et al, editors. *Rheumatology*. 3rd ed. St. Louis: Mosby; 2003, p. 641-50.)

movements most commonly seen in athletes (rowers, canoeists, weight lifters)⁴ and is associated with localized tenderness and swelling and palpable or audible crepitus with wrist flexion and extension. Most patients respond well to splinting, rest, antiinflammatory agents, and possibly an injection. Surgical release of the tendon sheaths of both compartments can be performed in refractory cases.²⁵

Trigger finger/thumb (stenosing digital tenosynovitis)

Trigger finger/thumb is one of the most common causes of pain and disability in the hand and occurs more frequently in patients with RA, diabetes mellitus, gout, and other conditions associated with connective tissue disorders.²⁶ The disorder is commonly limited to one digit but may be seen in multiple digits over time.

Tenosynovitis leads to fibrosis with constriction of the first annular pulley (A1) that overlies the MCP joint.²⁷⁻²⁹ A tendon nodule may develop and can be felt as a palpable mass in the palm that moves with the tendon as the digit flexes and extends. The nodule or tendon sheath constriction interferes mechanically with normal tendon gliding. Intermittent locking of the digit in flexion may also occur and is most frequently

noted on awakening. Over time, not moving the joint can lead to flexion deformity.⁴

Early management may consist of modification of hand activities, heat therapy, gentle exercises, and antiinflammatory medications as required.^{27,28} Extension splinting of the affected digit at night prevents the painful locking of the digit most often found in the morning.

Sometimes, trigger finger or thumb may resolve spontaneously. Corticosteroid injection is often curative, with success rates of up to 85%.^{26,30,31} Insulin-dependent diabetes has been identified as a significant independent predictor of failure of relief from an injection alone.³² If corticosteroid injection fails, surgical release of the A1 pulley is indicated.^{29,33}

Ganglions of the wrist and hand

Ganglions are cystic masses arising from a nearby joint capsule, tendon, or tendon sheath. They are the most common soft tissue tumor in the hand (50% to 75% of all masses), and they commonly occur in women in their 20s and 30s.⁴ Ganglions are lined with synovial tissue and contain a clear, gelatinous fluid. They are typically thin walled and may be unilocular or multilocular. Some may be quite large; others are occult and seen only on magnetic resonance imaging (see Fig. 75.7).

Ganglion cysts most commonly arise on the dorsal surface of the wrist (60% to 70%) and can typically be traced by their stalk to the capsule overlying the scapholunate ligament.³⁴ The second most common location is the volar radiocarpal joint (20%).⁴ Ganglions also arise as cysts of the tendon sheath from the A1 pulley, as mucinous cysts related to DIP joint arthrosis, or along any of the extensor and flexor tendons.

Ganglions are typically painless, well-circumscribed swellings on the dorsum of the wrist. They may cause mild to moderate discomfort when performing activities such as push-ups or other motions that load the wrist in an extended position. Most patients seek treatment because of the appearance of the ganglion rather than its functional limitation. They may note that the mass has changed in size over time—becoming larger for a while and then regressing. The mass may be palpably firm or soft, depending on how tense the cyst is when examined. Patients with symptoms of ulnar or median nerve compression should be evaluated closely because a space-occupying mass such as a ganglion in the canal of Guyon or the carpal tunnel can elicit these symptoms.^{35,36}

Radiographs of the affected region may demonstrate soft tissue swelling, but ultrasonography or magnetic resonance imaging may be required to better delineate the ganglion and trace its origin back to a joint capsule or tendon sheath or to detect intraosseous ganglions.³⁵

Histologically, a ganglion consists of compressed collagen fibers partially lined by fibroblast-like cells, similar to synovium.³⁵ Typically, minimal inflammatory tissue is present. The stalk of the ganglion may take quite a circuitous path as it connects from the joint or tendon sheath to the main body of the cyst. The liquid inside a cyst is a clear, viscous, gelatinous-type fluid containing high levels of hyaluronic acid, glucosamine, albumin, and globulin.⁴

The etiology of ganglion cysts is poorly understood. Although most patients cannot recall a specific traumatic event, it is thought that mild repetitive trauma may thin or tear the joint capsule or tendon sheath and allow the egress of fluid into a subcutaneous location. Arthrography has shown that intraarticular fluid will enter the cyst, but cystograms typically show that the cystic fluid does not reenter the joint, thus indicating that the stalk must include a type of one-way valve.³⁷ The valvular mechanism may explain why aspiration or simple excision of the ganglion without removal of the stalk can result in a recurrence rate of 50%.³⁸

Treatment of dorsal wrist ganglions begins with reassuring the patient that the condition does not require treatment unless it is causing difficulty. Home remedies such as hitting the cyst with a large book are not recommended. Ganglion cysts may change size over time and can disappear spontaneously. Aspiration may lead to complete resolution, but as noted earlier, recurrence is quite common. Aspiration of cysts in some areas may be less of an indication because of the risk of damaging neurovascular structures. Surgery is indicated when symptomatic ganglions fail to respond to more conservative methods. After surgical excision, including eradication of the capsular stalk, the rate of recurrence is less than 5%.³⁸ Wrist ganglions have also been treated successfully by arthroscopic elimination of the stalk from within the joint.³⁹

Carpal tunnel syndrome

Carpal tunnel syndrome is usually associated with burning or tingling sensations or numbness (or both) over the volar aspect of the radial three digits. Pain at night and difficulty sleeping are commonly noted.

Uncommon in the young, carpal tunnel syndrome is most often an idiopathic disease of aging. Pressure on the nerve is increased as it passes through the relatively restrictive carpal tunnel along with nine flexor tendons. Any swelling in this area as a result of tenosynovitis, fluid retention, trauma, or arthritis may decrease the space available for the nerve and can cause symptoms. Pregnancy, thyroid disease, rheumatoid and other inflammatory arthritic conditions, and diabetes are also associated with carpal tunnel syndrome.

On physical examination, patients may have decreased two-point discrimination in the median nerve distribution and, in later stages, weakness of the thenar musculature. Testing of the abductor pollicis brevis by resisted palmar abduction is important. Many patients may not be able to exactly articulate or distinguish the regions of sensory deficit, and some will have objectively decreased two-point discrimination in the ulnar two digits as well, possibly related to increased pressure in the canal of Guyon related to the underlying carpal tunnel syndrome. Tenosynovitis of the digital flexors may be noted especially in the inflammatory arthropathies. Provocative testing includes elicitation of the Tinel sign (distally radiating altered sensibility with percussion of the median nerve just radial to the palmaris longus at the level of the volar wrist crease) and performance of the Phalen test (reproduction of symptoms with the wrist held in gravity-assisted flexion with the elbows extended for 60 seconds) and Durkin test (reproduction of symptoms with pressure applied continuously over the carpal tunnel). Atrophy is a late finding associated with long-standing compression. Many patients respond to nonoperative management consisting of modification of activity, nighttime splints, antiinflammatory medications, and possibly corticosteroid injection. If such treatment fails, nerve conduction testing should be undertaken to confirm the diagnosis. Surgical release of the carpal tunnel may be indicated for relief of symptoms and to prevent further nerve damage. Surgery is the definitive treatment in older patients with chronic numbness, muscle weakness, and symptoms lasting for longer than 6 to 12 months. In patients with comorbid conditions such as mucopolysaccharidoses, dysplasias, endocrine disorders, inflammatory conditions, and connective tissue abnormalities, a surgical procedure is more commonly necessary for treatment.⁴⁰

Dupuytren disease

Dupuytren disease or contracture is a usually painless hereditary condition in which the palmar fascia (aponeurosis) becomes markedly thickened. It may cause small lumps or nodules to form deep to the skin at the base of the digits or in the palm, and pitting of the skin may be noted.^{41,42} The ring finger is most commonly affected, followed by the small and long fingers. Bilateral disease is not uncommon. The myofibroblast is the cell type associated with this condition. Contraction of myofibroblasts in the palmar fascia leads to the early nodular findings. The skin may become involved through local invasion by fibroblastic cells, which results in pitting (Fig. 75.9). Despite being called “local invasion,” Dupuytren disease is noncancerous. In some patients the disorder may never progress from the nodular stage and thus may not require further medical treatment. In most patients, increasing thickening with extension into the digits will develop gradually over a period of months to many years and lead to restriction of motion and flexion contracture. The tendons and joints are not involved with the Dupuytren tissue.

Many patients will not notice or complain of the condition until bands or cords have formed that gradually contract and cause the affected digits to become flexed toward the palm. Most patients will seek medical assistance when they are unable to flatten their hand against a tabletop or other smooth surface or when it becomes difficult to put their hand into a pocket or glove (see Fig. 75.9).

The cause of Dupuytren contracture is not well understood, and no definitive cure is available.^{41,42} It is seen most frequently in white patients of northern European descent. Men are affected seven times more often than women, and it is rarely seen in patients younger than 40 years.⁴ Patients can frequently identify another family member who has had similar findings, thus indicating an autosomal dominant condition with variable penetrance. Trauma has not been proved to be an associated cause.^{41,42}

A more severe and aggressive form of the condition called “Dupuytren diathesis” can affect other parts of the body, including the soles of the feet, the popliteal fascia, the knuckle pads, and the penis. Symptoms frequently develop in these patients at an earlier age.

Treatment depends on how much contracture exists, how rapidly the contracture is progressing, and the functional disability that the patient is experiencing. With mild disease, local application of heat, stretching exercises, and use of protective gloves may be helpful.^{4,41,42} Splinting does not appear to alter progression of the disease. In patients with a painful nodule,

Fig. 75.9 Dupuytren contracture of the ring finger. (a) Pitting of the skin and a longitudinal cord causing flexion of the metacarpophalangeal (MCP) joint can be seen. (b) A contracture/flexion deformity at the MCP joint keeps this patient from flattening his hand against a flat surface.

intralesional corticosteroid injections may provide symptomatic aid.⁴¹⁻⁴³ For patients with progressive deformity or a static contracture greater than 30 degrees at the MCP or PIP joints or those with functional impairment, treatment is indicated. The standard of care remains limited or total surgical palmar fasciectomy with or without skin grafting.⁴⁴ A newer alternative treatment—injection of *Clostridium* collagenase into the cords to weaken them and allow corrective manipulation—has been shown to be equally effective.⁴³ Despite successful treatment with collagenase or surgical

excision, the risk for recurrence in the same digits or new formation of disease in other digits is significant. This risk is increased in younger patients with aggressive bilateral disease, in those with a strong family history, and in patients with fibrotic lesions elsewhere in their body.⁴⁴ Sometimes the disease has progressed to the point that the MCP or PIP joint capsules have become significantly contracted, and in such cases, full digital extension may not be possible without extensive joint release and neurovascular risk.

The hip

■ SIMON GÖRTZ ■ KEVIN B. FRICKA ■ WILLIAM D. BUGBEE

- Hip pain is a common symptom with diverse causes, but most cases can be diagnosed with a careful history, a thorough physical examination, and appropriate radiologic evaluation.
- Even though radiographs often lag behind actual pathologic changes, most intraarticular hip disorders can be effectively diagnosed radiographically, and standard hip and pelvis views should be obtained routinely.
- The role of magnetic resonance imaging in the diagnosis of hip pathology is evolving and becoming increasingly reliable.
- Hip pain in a young, active individual should raise a high index of suspicion for labral pathology.
- The differential diagnosis of unexplained hip pain should include osteonecrosis, even in lieu of apparent risk factors.
- Hip dysplasia describes bony dysmorphisms that affect either component of the hip joint as a result of developmental anomalies and lead to decreased coverage of the femoral head.
- The concept of femoroacetabular impingement describes the situation of mechanical conflict between a morphologically abnormal proximal femur and acetabular rim.

FUNCTIONAL ANATOMY

Bony structures

The hip joint is a ball-and-socket synovial joint in which the head of the femur articulates with the cup-shaped acetabulum (Figs. 76.1 and 76.2). Despite the resulting degree of stability, the hip joint possesses multiaxial mobility in the sagittal, transverse (rotational), and frontal planes, with the greatest freedom sagittally. The motion required for performing activities of daily living is flexion of at least 120 degrees, abduction of 20 degrees, and rotation of 20 degrees, although sporting activities often necessitate greater range of motion.

The acetabular cup is approximately 45 degrees abducted and 15 degrees anteverted and encompasses the femoral head. This bony socket is deepened by the fibrocartilaginous labrum, which augments femoral coverage circumferentially around the perimeter of the acetabulum except at its base, where it continues as the transverse acetabular ligament. The articular cartilage surface of the acetabulum resembles a horseshoe, the central cavity of which is occupied by the pulvinar, a fat pad covered by synovium. The concave opening, or acetabular fossa, lies inferomedially and gives rise to the ligamentum teres, which inserts at the fovea capitis, a small divot in the medial femoral head. Although the fovea itself is devoid of cartilage, the remaining articulating two thirds of the femoral head possesses cartilage varying in thickness from 3 mm in the posterosuperior segment to 1 mm peripherally, which reflects varying degrees of weight-bearing demand (Fig. 76.3).

The anatomy of the proximal end of the femur is composed of the head/neck and intertrochanteric segments. In most hips the center of the femoral head lies at the level of the tip of the greater trochanter, the bony prominence where the gluteal muscles insert laterally. The smaller lesser trochanter is situated medially and serves as insertion point for the hip flexors (iliopsoas). The head/neck segment lies about 15 degrees anteverted in relationship to the shaft of the femur. The normal neck-shaft angle is between 125 and 140 degrees. *Coxa valga* is the term referred to when this

angle increases above this range and *coxa vara* when the angle decreases below this range (Fig. 76.4).

Joint capsule

Contributing to the stability of the hip joint is the strong and dense fibrous capsule. It attaches around the periphery of the acetabulum just outside the labrum and inferiorly along the transverse acetabular ligament. On the femur, the capsule inserts along the intertrochanteric line anteriorly and continues posteriorly just proximal to the intertrochanteric crest, which results in more than 95% of the femoral neck being intracapsular. The capsule is strengthened by three prominent reinforcements: the iliofemoral, the pubofemoral, and the ischiofemoral ligaments. The iliofemoral ligament, also referred to as the Y ligament of Bigelow, is the strongest and most important. It resembles an inverted letter Y and originates at the anterior inferior iliac spine, with its diverging fibers fanning out over the anterior aspect of the hip joint to insert distally along the intertrochanteric line. This ligament prevents excessive extension and helps maintain an erect posture since it is taut in extension and relaxed in flexion. These ligaments all coil and tighten in extension, thus making this the position of maximum stability for the hip joint.

Hip musculature

The hip joint and its surrounding musculature function to meet the requirements of efficient walking. To accomplish this, the hip girdle must maintain stability of the weight-bearing limb despite changes in limb and body position as it propels the body forward. The origins and insertions of the surrounding hip musculature are shown in Figures 76.1 and 76.2. The primary hip flexors are the iliopsoas, rectus femoris, and sartorius. The gluteus maximus and the hamstring muscles (long head of the biceps femoris, semimembranosus, and semitendinosus) are the primary hip extensors. Abduction of the hip joint is accomplished by the gluteus medius and gluteus minimus. The adductor group consists of the adductor longus, adductor magnus, adductor brevis, gracilis, and pectineus. The short external rotators, which extend across the posterior aspect of the hip capsule, include the obturator internus and externus, the superior and inferior gemelli, the quadratus femoris, and the piriformis muscles. The hip has no primary internal rotators, but many muscles do so secondarily, such as the anterior fibers of the gluteus medius.

Bursae

Along with the many muscles groups surrounding the hip joint, several prominent bursae facilitate gliding of soft tissues over areas of potential friction. Since they are lined with synovial tissue, they may be affected by any of the inflammatory diseases that can involve the hip joint, such as rheumatoid arthritis and infectious or crystal-induced synovitis. Most commonly, however, bursitis and tendonitis around the hip are induced by trauma or repetitive microtrauma.

The trochanteric bursa lies between the gluteus maximus and the posterior lateral aspect of the greater trochanter, the iliopsoas bursa lies anteriorly between the hip capsule and the iliopsoas tendon, and the ischiogluteal bursa lies posteriorly between the gluteus maximus and the ischial tuberosity.

Blood supply

Although the hip joint itself is well perfused, the tenuous vascular anatomy of the femoral head makes it highly susceptible to avascular necrosis as a

Fig. 76.1 Muscular and capsular attachments of the proximal end of the right femur. Anterior and posterior views of the proximal end of the right femur show the attachments of the muscles and hip capsule.

result of injury, dislocation, or fracture of the femoral neck. The femoral head is supplied by the terminal ascending branches of the medial femoral circumflex artery, a branch of the profunda femoris artery.^{2,3} These small, delicate branches run along the posterior superior aspect of the neck and perforate the femoral head near its base. In developing children, the metaphyseal and epiphyseal blood supplies are separate until physeal closure.³

CLINICAL EVALUATION

Hip pain is a common symptom with diverse causes, but most cases can be diagnosed with a careful history, a thorough physical examination, and appropriate radiologic evaluation.

History

Elucidating the characteristics of the pain is paramount, including the location, severity, and frequency of the pain. Onset, alleviating or aggravating factors, and radiation of the pain up or down the leg should also be noted.

Location of the pain

In the general sense, “hip pain” is often considered to include locations from the lower part of the back, pelvic girdle, and proximal aspect of the thigh. A classification of hip pain based on the tissues primarily involved in specific disorders is outlined in [Box 76.1](#). Of these, osteoarthritis of the hip, trochanteric bursitis, and spinal disorders account for the vast majority of conditions seen in clinical practice. True intraarticular hip pathology will most often cause groin pain plus occasional radiation to the knee, with the pain being referred along the continuation of the obturator and femoral nerves via their respective sensory articular branches in the hip capsule. Radiation to the anterior, medial, or lateral aspect of the thigh is quite common. The most frequent cause of lateral pain is generally related to trochanteric bursitis. Lumbar pathology most often refers pain to the posterior aspect of the hip area, and radicular symptoms usually radiate pain posteriorly along the buttock and below the knee. Posterior hip and buttock pain can also be referred from the sacroiliac joints. If associated with an insidious onset and severe morning stiffness that is relieved by activity, the diagnosis of sacroiliitis is usually considered. In cases in which the history

Osseous

Bone lesions
 Fractures, neoplasms
 Infection
 Osteonecrosis of the femoral head
 Paget disease
 Metabolic bone disease
 Stress fracture
 Transient osteoporosis
 In children
 Congenital dislocation of the hip
 Acetabular dysplasia
 Coxa vara
 Slipped capital femoral epiphysis
 Legg-Calvé-Perthes disease
 Rickets

Neurologic

Entrapment neuropathies
 Lateral femoral cutaneous nerve
 (meralgia paresthetica)
 Lumbar nerve root compression
 L2, L3, and L4

Vascular

Atherosclerosis of aorta iliac vessels

Referred pain

Thoracolumbar spine
 Intraabdominal structures
 Retroperitoneal structures

patient's recreational and occupational functions should be discussed, and any alterations in these activities should be sought. Previous treatments, including forms of self-treatment, physical therapy, and medications, along with responses to these modalities, must also be explored.

The onset and character of the pain are worth noting in an effort to distinguish pain at rest, which indicates an underlying, more advanced degenerative process, from mechanical activity-related pain, which suggests soft tissue injury or early degenerative disease.

Further questioning to characterize the alleviating or aggravating factors can help differentiate certain disorders. Degenerative joint arthropathy is usually exacerbated by activity and subsides with rest. If the pain persists with rest, an infectious or inflammatory process should be suspected. Prolonged morning stiffness relieved by activity is typical of an inflammatory arthropathy. Pain aggravated by lying on the affected side is highly suggestive of trochanteric bursitis, whereas buttock pain aggravated by sitting suggests ischiogluteal bursitis. Posterior buttock pain with radiation can be associated with lumbar pathology if symptoms arise with the spine in an upright or extended position, if flexion or leaning forward alleviates the pain, and if the symptoms do not immediately resolve with rest. A vascular etiology should be suspected if the pain is aggravated with any muscular activity and relieved within minutes of rest. A careful history may reveal previous catheterization or other trauma to the femoral vessels.

General enquiry

The history should also include questions about childhood hip disorders (sepsis, developmental dysplasia, Legg-Calvé-Perthes disease, slipped capital femoral epiphysis), previous problems or injuries involving the hip, and previous treatment or surgery. A history of a recent increase in activity should be questioned to rule out stress or overuse injuries. Significant medical factors potentially relating to hip pathology should be sought. Such factors include a previous history of trauma, corticosteroid use, alcohol use, coagulopathies, immune-mediated or inflammatory disorders, and malignancies. This information can provide insight into conditions such as avascular necrosis, pathologic fracture, or the inflammatory arthritides.

Examination

Apart from a detailed examination of the hip, a thorough physical examination requires detailed assessment of the relevant neurologic, muscular, and vascular systems. Neurologic examination, in addition to manual muscle testing, should include assessment of normal sensation to light touch and palpation. Vital signs, including temperature, should be recorded because septic arthritis should be ruled out in patients with hip pain and fever.

Gait examination

Inspection is the first tenet of a thorough physical examination and begins with watching the patient walk into the examination room. The physician should evaluate patients' gait, how they rise from a chair, what type of posture they assume, and how much disability they exhibit. Gait analysis is a complex science; nonetheless, a physician evaluating hip disorders should be able to assess and classify slight, moderate, and severe limps. The normal walking cycle has two phases: the weight-bearing stance phase, which begins with heel strike and ends with toe-off, and the non-weight-bearing swing phase between toe-off and heel strike. During the stance phase the

and physical examination are inconclusive in distinguishing the source of pain, therapeutic corticosteroid injections into the lumbar epidural space or the sacroiliac joint can be helpful in differentiating lumbar pathology, sacroiliitis, and hip pain.

Assessing characteristics and impact

The severity of the pain is best assessed in terms of the patient's ability to perform functional activities such as getting in and out of a car, climbing stairs, taking care of foot hygiene, or sitting comfortably in low chairs. The

hip joint loads three times the patient's body weight, and the length of time spent in single-leg stance by the patient will provide insight into what type of limp is present.

General inspection

The patient should be standing up and adequately disrobed for a proper examination. Note any atrophy or asymmetry and previous surgical scars. Assess for pelvic obliquity by placing a finger above both iliac crests and checking whether they are level. Pelvic obliquity suggests a discrepancy in leg length or a contracture of the hip causing compensatory obliquity. The resting posture of the hip that causes the least pressure within the joint is the flexed, abducted, and externally rotated posture. Patients with acute synovitis or inflammatory effusions may be resting in this position to help splint the pain.

Palpation

Palpation should begin in the standing position as well because this makes it easier to feel all bony landmarks, including the iliac crest, greater trochanter, ischial tuberosity, pubic symphysis, posterior superior iliac spine, and anterior superior iliac spine. Tenderness in some of these areas is suggestive of certain pathologies. Pain with palpation over the greater trochanter is very probably consistent with bursitis, and pain over the pubic symphysis can signal osteitis pubis or athletic pubalgia.

Range of motion

The supine position is best to assess passive and active range of motion of the hip, both of which should be tested in all planes: flexion, extension, adduction, abduction, external rotation, and internal rotation. In the general population normal range of motion is considerably variable, so the examiner should always measure both sides for comparison⁴ while keeping in mind that the comparison side can also exhibit pathology with bilateral disease. Normal flexion should be between 100 and 135 degrees. Similarly, extension of the hip should be from 0 to between 15 and 30 degrees. Abduction and adduction testing is done with the patient supine, and stabilization of the pelvis must be performed to record accurate values. During testing the patient's pelvis should be level and balanced, and no pelvic motion should take place. Normal hip abduction should achieve 40 degrees and adduction 30 degrees from neutral. Rotational motions of the hip are best measured with the hip flexed but also can be done with the hip extended by using the logroll maneuver, which is less sensitive but more specific when assessing for intraarticular pathology. From the neutral position, internal rotation is normally between 30 and 40 degrees. External rotation is usually greater, between 40 and 60 degrees. The first motions that typically diminish in patients with hip arthrosis are internal rotation and abduction. An increase in internal rotation greater than normal is generally indicative of rotational deformities about the proximal end of the femur, such as seen with increased femoral anteversion and dysplasia.

Special tests

Patrick test (FABER test)

The Patrick test is helpful in detecting limited hip motion and distinguishing hip pain from sacroiliac disease. The test is sometimes referred to by the acronym FABER, derived from the initial letters of the movements that it evaluates (*flexion, abduction, external rotation*) (Fig. 76.5).

With the patient lying supine, the knee and hip are flexed to 90 degrees and the foot of the examined extremity is placed on top of the opposite knee ("figure 4" position). The thigh is then slowly abducted fully and externally rotated toward the examining table. The presence of groin pain, spasm, or limitation of movement is suggestive of hip pathology. The Patrick test can also be used to stress the sacroiliac joints. To do so, one hand is placed on the abducted knee and the other on the opposite anterior superior iliac spine. Pain localized to the back when sudden pressure is applied simultaneously on each of these points suggests sacroiliac pathology.⁵

Thomas test

The Thomas test quantifies flexion contracture of the hip by stabilizing the pelvis and eliminating compensatory lumbar lordosis. With the patient lying supine, the thigh opposite the side to be tested is fully flexed on the abdomen to flatten the spine and stabilize the pelvis. This leg is then held in position and the examined limb allowed to extend to neutral. Failure of the hip under observation to lie flat on the examining table allows easy measurement of the degree of fixed flexion (Fig. 76.6).

Stinchfield test

This test is performed in the supine position with the knee extended. The patient is asked to actively elevate the leg while gentle manual resistance is

Fig. 76.5 To perform the Patrick test (FABER test), the contralateral iliac crest is stabilized with downward pressure while lowering the ipsilateral flexed, abducted, and rotated leg. Groin pain suggests hip pathology, whereas posterior pain suggests sacroiliac disease.

Fig. 76.6 A flexion deformity of the hip is masked by increased lumbar lordosis (top). With the Thomas test, flexion of the contralateral hip flattens the lordosis and reveals the flexion deformity of the hip (bottom).

applied by the examiner. A positive response suggesting hip pathology would be reproduction of pain in the groin, thigh, buttock, and occasionally the knee, a typical pattern related to the sensory innervation of the hip. Back pain suggests a spinal cause.

Apprehension tests

These set of dynamic maneuvers are provocative tests that evaluate for the presence of labral pathology. With the patient lying supine on the examination table, the examiner moves the hip from a flexed, externally rotated and

abducted position to an extended, internally rotated and adducted position. This set of motions tests for anterior labral pathology, and reversing the maneuver will test for posterior pathology. The presence of labral pathology will usually produce a painful click or a searing sensation in the groin or deep anterolateral symptoms.⁶ This should be compared with the contralateral side because such tests may cause minor discomfort even in a healthy hip.

Leg length measurement

Measurements of leg length are best performed with the patient lying supine and the legs fully extended and placed 15 to 20 cm apart. Measurements are made for both true and apparent leg length inequality. True leg length measurements are made between fixed bony landmarks, from the anterior superior iliac spine to the middle of the lateral and medial malleoli. Apparent leg length inequality is measured from a fixed point in the center of the body, usually the umbilicus, to the middle of the medial and lateral malleoli. Standing radiographs of the pelvis can be used to detect leg-length discrepancy as well. In the absence of contracture and pelvic obliquity, a difference in the height of the femoral heads indicates leg length inequality.⁷ A difference in length between the two legs of 1 cm or less is not generally clinically significant. An apparent (or functional) leg-length discrepancy on inspection may result from a pelvic tilt secondary to scoliosis or contractures of the hip (Fig. 76.7). In these situations, measurements from the umbilicus will show an apparent shortening of the leg on the side with the higher pelvis. However, when measured from the anterior superior iliac spine, the legs will have the same length.

True leg-length discrepancy can be due to various congenital or acquired disorders. The most common of these disorders include congenital dislocation of the hip, acetabular dysplasia, Legg-Calvé-Perthes disease, slipped capital femoral epiphysis, and congenital coxa vara. Leg-length discrepancy is associated with an increased incidence of trochanteric bursitis on the longer leg, which is typically held in adduction under a tilted pelvis. This results in decreased covering of the femoral head by the acetabulum. The increased localized stress on the remaining weight-bearing area of the femoral head may contribute to the development of osteoarthritis.⁸

Fig. 76-7 Functional shortening of the affected leg may be due to adduction deformity of the right hip.

RADIOGRAPHIC EVALUATION

Plain radiographs

Most intraarticular hip disorders can be effectively diagnosed radiographically. Thus, complete evaluation of a patient with hip pain should include an anteroposterior view of the pelvis and either true cross-table or frog-leg lateral views of the hip. Obtaining a pelvis view that includes both the right and left hips makes a built-in comparison readily available (Fig. 76.8). The clinician should use these radiographs to assess for fractures, leg-length discrepancy, extent of degenerative or inflammatory arthropathy, evidence of dysplasia or other deformities, and the occurrence of abnormal calcification or ossification as seen with calcific bursitis or sacroiliitis, respectively. Although plain radiographs cannot be used to diagnose fluid in the hip joint, labral pathology, chondral defects, unmineralized loose bodies, or tendon disorders, they may provide clues to sources of referred pain such as ureteral stones, lumbar pathology, or severe calcific vascular disease.

Other imaging

Depending on what is learned from these initial radiographs, further imaging studies may be warranted. If the clinician is concerned about fluid in the hip joint, ultrasound evaluation is most efficient and cost-effective in determining the amount of fluid and the possible need for joint aspiration. Bone scans can be useful for evaluation of bone metabolism and osseous pathology such as occult femoral neck fractures. However, magnetic resonance imaging (MRI) has been shown to be more cost-effective when evaluating for occult femoral neck fractures because of earlier detection.⁹ The role of MRI in the diagnosis of hip pathology is evolving and becoming increasingly reliable with the development of specialized protocols and high-resolution scanners using bigger magnets. Although cost is an issue, MRI is most valuable in assessing for the presence of avascular necrosis of the femoral head, but it can also be used for detecting fluid in the hip joint or extraarticular soft tissue abnormalities. The addition of gadolinium-enhanced arthrography has increased sensitivity in detecting intraarticular pathology such as articular cartilage delamination or fragmentation and labral changes, including hypertrophy, tears, and associated paralabral cyst formation (Fig. 76.9).

Role of imaging in clinical practice

Even though radiographs often lag behind actual pathologic changes and are unimpressive in the early stages of disease, they will usually show characteristic changes over time, and the diagnosis should pose little difficulty. For instance, it is easy to diagnose Paget disease of the femur and hip joint (abnormal bone remodeling showing coarsened trabeculae, a blastic appearance, and remodeled cortices). Similarly, primary hip osteoarthritis is readily diagnosed in the presence of subchondral sclerosis, marginal osteophytes, and superolateral joint space narrowing. The same applies to late stages of

Fig. 76-8 Anteroposterior view of the pelvis demonstrating right hip dysplasia (arrow) and a normal contralateral hip. This view allows a built-in comparison.

Fig. 76-9 Magnetic resonance arthrogram of the hip demonstrating slight effusion and a superior labral tear (arrow).

osteonecrosis when flattening of the femoral head has occurred or to chondrocalcinosis when calcific deposits are visible in hyaline cartilage or the acetabular labrum. Inflammatory arthritis may be suspected when subchondral erosions, osteopenia, and minimal joint space narrowing without osteophytes or sclerosis are present. In other more difficult cases the radiographic findings are abnormal but are not characteristic of a specific disorder. Bone pathology may be suspected by the presence of localized or diffuse osteopenia or sclerosis of the femoral head, neck, or acetabulum. Diagnosis and management are even less obvious when patients have hip pain and normal radiographic findings. In these circumstances, further diagnostic modalities should be guided by a careful history and physical examination. Clinical suspicion of early osteonecrosis may require MRI for confirmation. An arthrogram may be helpful in documenting chondromatosis, synovial tumors, and labral tears, as well as local thinning, cystic changes, delamination, or fragmentation of cartilage in the weight-bearing areas of an early osteoarthritic joint. Suspicion of chronic septic or crystal-induced synovitis would require joint aspiration for analysis of synovial fluid. Limitation of hip movements in all directions in a diabetic patient suggests adhesive capsulitis of the hip joint. The presence of systemic symptoms, such as fatigue, fever, weight loss, or worsening of pain at night, suggests infection or malignancy.

SPECIFIC HIP DISORDERS

Hip disorders that occur as part of a generalized rheumatologic problem such as osteoarthritis, rheumatoid arthritis, and ankylosing spondylitis are covered elsewhere in this volume. This chapter focuses on other hip- and hip area-specific conditions.

Hip dysplasia

Hip dysplasia describes bony dysmorphisms that affect either component of the hip joint as a result of developmental anomalies and lead to decreased coverage of the femoral head (see Fig. 76.8).¹⁰ Excessive vertical slope of the acetabulum with valgus angulation of the femoral neck is generally considered a hallmark of classic dysplasia and can be associated with excessive anteversion or retroversion of the acetabulum. The femoral head is commonly aspherical and situated laterally in the acetabulum, thus making the labrum part of the weight-bearing surface of the acetabulum.¹¹ The vertical center edge (CE) angle of Wiberg can be determined from an anteroposterior radiograph to assess the amount of femoral head coverage. The CE angle is measured between a line connecting the lateral edge to the center of the femoral head and a vertical line extending from the center of the head. A normal CE angle is greater than 25 degrees, whereas it is less than 20 degrees in a dysplastic hip. Values between 20 and 25 should be considered borderline dysplastic. Likewise, a vertical center anterior angle can be derived from a false profile lateral view to measure sagittal version and assess anterior coverage of the head.¹⁰ Labral tears are a common feature in hips with subtle or severe dysplasia.¹¹ Thus, any patient

Fig. 76-10 Lateral view of the left hip demonstrating bony buildup (arrow) with loss of sphericity at the femoral head-neck junction.

with a known labral tear should be evaluated carefully for underlying hip dysplasia.

Femoroacetabular impingement

The concept of femoroacetabular impingement (FAI) describes the situation of mechanical conflict between a morphologically abnormal proximal end of the femur and acetabular rim. Repetitive abutment, especially during terminal flexion and internal rotation, leads to cumulative damage to the labrum and subsequently delamination or ulceration of the articular cartilage overlying the adjacent acetabular rim.¹²

Subtypes

Two types of FAI are recognized and defined by their etiology. In cam-type FAI, the primary site of malformation is the femur, whereas in the pincer type, it is the acetabular component that is dysmorphic. The cam type is characterized by an increased radius of the neck-head junction with loss of sphericity, either primarily because of lack of head offset or as a result of bony buildup secondary to pincer-type FAI. Repetitive trauma to the labrum from impingement by the neck segment in flexion and internal rotation results in damage to cartilage and ultimately labral-osseous separation, mostly in the anterior-superior region. Conditions associated with the development of cam-type impingement include femoral neck retroversion and a history of slipped capital femoral epiphysis or Legg-Calvé-Perthes disease.¹³ Pincer-type FAI results from lack of acetabular clearance, which leads to linear contact between the anterior acetabular rim and head-neck junction. The resulting relative overcoverage of the femoral head causes increased impaction and ultimately failure of the labrum and, with subsequent rim ossification, worsening overcoverage and abutment, which can lead to kissing lesions on the femoral neck. Associated conditions include coxa profunda, protrusion, acetabular retroversion, and a history of acetabular fracture.¹² Demographically, cam impingement typically occurs in young athletic males with labral tears, whereas pincer impingement is more common in middle-aged active woman and usually has a more benign course.

Clinical features

Typically, patients will experience intermittent, progressive activity-related groin pain with occasional mechanical symptoms. Pain in the position of impingement (flexion, internal rotation, adduction), especially after prolonged sitting, is commonly present.

Findings on physical examination include decreased motion in internal rotation and adduction in flexion. The impingement maneuver is part of the apprehension test and is performed by internally rotating and then adducting and flexing the patient's hip to 90 degrees. This causes a shearing force at the labrum or chondral surface and reproduces the symptoms.⁶

Imaging

Radiographic evidence is usually subtle, but close scrutiny may reveal bony prominence of the femoral head-neck segment (Fig. 76.10), as well as

flattening and reduced offset of the anterolateral neck (pistol grip deformity). Rim ossification/os acetabuli and herniation pits can also be assessed and allow evaluation of the status of the acetabular cartilage at the impingement site.¹² Suspicion for FAI with inconclusive screening radiographs should be followed by special lateral views or three-dimensional tomography with surface rendering, which is usually accurate in diagnosing the underlying pathology.

Treatment

Over the last decade, hip arthroscopy has advanced to a common diagnostic and therapeutic modality. Even though arthroscopy has helped better define the periarticular and intraarticular pathoanatomy of hip disease, indications for its use are still evolving.¹⁴ Therapeutic use has advanced from simple débridement of the affected soft tissues or osteoplasty of a hyperplastic femoral neck or hypertrophic acetabular lip to arthroscopic repair of labral tears and articular cartilage repair procedures. In addition, surgical hip dislocation is increasingly being used to address morphologic contributors to FAI of the nondysplastic hip and to allow advanced restorative options in addressing osteoarticular lesions.¹⁵

Periarticular soft tissue problems

Several problems of the hip are related to the soft tissue structures around the joint and its surrounding muscles. Though relatively common, many of these problems are poorly defined, misdiagnosed, or both.¹⁶

Bursitis

Trochanteric bursitis

Trochanteric bursitis is the most common cause of pain about the hip region. Patients with trochanteric bursitis have deep, aching pain sometimes associated with a burning sensation on the lateral aspect of the hip and thigh that increases with activity and can be associated with a limp.¹⁷ Typically, the pain decreases at rest, although it is frequently worse at night, especially when the patient is lying on the affected side. Tenderness can be elicited by palpation of the area around the greater trochanter. The trochanteric bursa is not usually palpable unless it is distended or inflamed. Resisted abduction of the hip when the patient is lying on the opposite side may accentuate the discomfort. Hip range of motion is usually preserved, but in severe cases the discomfort can limit motion. Slight irregularities of the greater trochanter or peritrochanteric calcifications of the bursa are sometimes seen on plain radiographs. The course of trochanteric bursitis is varied: an acute phase may last several days, followed by gradual abatement of the symptoms, although low-grade discomfort may persist for weeks or months.

Treatment includes rest, as well as physical therapy for abductor and iliotibial band conditioning and stretching. Nonsteroidal antiinflammatory drugs (NSAIDs) can be used, but the results are often mixed. Infiltration of a local anesthetic and a long-acting corticosteroid preparation has been shown to be helpful in confirming the diagnosis and bringing long-term relief.^{16,17} It is considered by many to be the most effective treatment modality. Various surgical procedures, including bursectomy, have been proposed for refractory cases, but these are rarely needed.

Fig. 76-11 A computed tomography scan of a patient with rheumatoid arthritis shows an enlarged fluid-filled iliopsoas bursa (arrow) communicating with the hip joint and displacing the neurovascular bundle (arrowhead). (With permission from Letourneau L, Dessureault M, Carette S. Rheumatoid iliopsoas bursitis presenting as unilateral femoral nerve palsy. *J Rheumatol* 1991;18:462-3.)

Iliopsoas bursitis

The iliopsoas bursa may communicate with the hip joint in approximately 15% of adults. Thus, iliopsoas bursitis can be manifested in association with a variety of hip disorders, including osteoarthritis, rheumatoid arthritis, synovial chondromatosis, pigmented villonodular synovitis, osteonecrosis, and septic arthritis.¹⁸ The direction and degree of bursal enlargement will dictate the symptoms, and patients may have a painful inguinal mass, groin pain, varicosities secondary to femoral vein compression, or paresthesias secondary to femoral nerve compression.^{19,20} Computed tomography has been proposed as the best diagnostic test to document iliopsoas bursitis (Fig. 76.11). Treatment with bursography and the instillation of corticosteroids is an effective diagnostic and therapeutic modality. Occasionally, the symptoms persist after nonoperative measures such as physical therapy and NSAIDs. In these cases, surgical excision of the bursa is sometimes necessary.

Ischiogluteal bursitis

Ischiogluteal bursitis is most commonly seen in patients engaged in jobs that require long periods of sitting²¹ and thus is also known as “weaver’s bottom.” Patients complain of exquisite pain over the ischia that is aggravated by sitting and lying. Local tenderness on palpation of the ischial tuberosity is always found. Use of an 8- to 10-cm-thick rubber cushion with holes to accommodate the ischial prominences may alleviate the symptoms. Trunk and knee-to-chest stretching exercises while lying on the cushion should also be encouraged. Local injection of corticosteroid may be used in refractory cases, but the sciatic nerve, which passes just lateral to the bursa, must be avoided.

The knee

■ REZA MAYAHI ■ GURHAN ERTURAN ■ WILLIAM JACKSON ■ ANDREW PRICE

- The knee is a complex diarthrodial joint that forms a highly modified hinge between the distal end of the femur and proximal end of the tibia.
- Knee stability is provided by the osseous anatomy, four major ligaments (the anterior and posterior cruciate and medial and lateral collateral ligaments), the medial and lateral menisci, and the adjacent musculature, which together provide static and dynamic stability for the joint. Several bursae are distributed around the knee where soft tissues move against bony prominences or in fascial planes.
- Knee pain may arise from the joint itself or from periarticular tissues such as tendons and bursae, or it may be referred from distant sites such as the hip or femur.
- Accurate diagnosis of knee conditions can usually be made on the basis of findings on the history and physical examination. Standard investigations include synovial fluid analysis, conventional radiography, magnetic resonance imaging, and arthroscopy.

SKELETAL ANATOMY

The knee is a large synovial joint formed between the articulation of the distal end of the femur, proximal end of the tibia, and the patella. Three separate compartments are recognized in the knee: medial tibiofemoral, lateral tibiofemoral, and patellofemoral (Fig. 77.1). The knee joint functions as a modified hinge joint that allows flexion and extension, together with some limited rotation.

Distal femur

The distal end of the femur has an asymmetric bicondylar shape, with a larger medial femoral condyle and a smaller, more rounded lateral femoral condyle. The patella articulates with the trochlear groove on the distal end of the femur, and the extension of this region forms the intercondylar notch, which contains the femoral origins of the anterior cruciate ligament (ACL, posterolateral) and the posterior cruciate ligament (PCL, anteromedial).

Proximal tibial plateau

The medial and lateral tibiofemoral compartments are formed by the articulation of the distal end of the femur with the convex articular surface of the lateral tibial plateau and the concave surface of the medial tibial plateau. The medial condyle is concave and longer in the anteroposterior plane to accommodate the medial femoral condyle. They are separated by the tibial spines, which are closely related to the insertion of the ACL.

Patella

The patellofemoral joint is formed by the articulation of the trochlea and patella. The patella is the largest sesamoid bone in the body, and it engages the trochlea when the knee is flexed more than 30 degrees. It increases the lever arm available to the quadriceps muscle in extending the knee, thereby leading to large forces acting across this compartment. To accommodate these high loads, the patellar articular cartilage is specially adapted such that it reaches up to 7 mm in depth, thicker than any other articular cartilage in the body.

SOFT TISSUE ANATOMY

The bones of the knee joint are connected together by five major ligamentous structures: the medial collateral ligament (MCL), lateral collateral ligament (LCL), ACL, PCL, and the posterior capsule (Figs. 77.2 and 77.3). The fixed attachments of the ligaments, which interact with the shapes of the articular surfaces, guide the motion of the knee driven by muscle activity.

Ligaments

The MCL is a broad flat ligament with superficial and deep layers. The superficial layer arises from the medial epicondyle and inserts over a broad area of the medial aspect of the proximal end of the tibia; it extends approximately 8 cm distally, below the joint line. The deep layer originates with the superficial layer and inserts into the medial meniscus just above the joint line. The LCL is smaller and more rounded in cross section, arises from the lateral femoral condyle, and inserts into the fibular head. These collateral ligaments provide varus and valgus stability to the knee joint.

The ACL and PCL lie within the center of the knee and form a four-bar linkage system. They act together to control anteroposterior and rotational movement within the knee. Both ligaments are intraarticular but extrasynovial and consist of two bundles. The bundles spiral around each other and insert on the anteromedial aspect of the tibia; they work synergistically to resist excessive anterior translation and internal rotation of the tibia relative to the femur.

The posterior capsule is augmented on the lateral side of the knee by the following structures: the popliteus tendon, the arcuate ligament, the popliteofibular ligament, the biceps femoris tendon, and the LCL. This constellation of soft tissue structures forms the “posterolateral” corner and helps control mainly rotation of the knee.

Menisci

The medial and lateral menisci are load-sharing crescentic disks of fibrocartilage that lie interposed between the femur and tibia. They act primarily to distribute load in the tibiofemoral compartment and thereby reduce contact stress, but in addition they help stabilize the joint. In cross section the menisci are triangular, thickest at the periphery and thinning on their inner concave aspect. Collagen fibers are aligned within the menisci to absorb hoop stress and dissipate compressive loads. The menisci are attached to the tibial surface at the intercondylar eminences. In addition, the semicircular medial meniscus is closely attached to the medial capsule and collateral ligaments by coronary ligaments. The smaller lateral meniscus forms a nearly complete circle and has a looser peripheral attachment, including a hiatus in the posterolateral capsule through which the popliteus tendon enters the knee.

The peripheral third of both menisci are vascularized through capsular attachments, thus offering potential for the structures to heal after injury. In contrast, the central third of the menisci, known as the “white zone,” is avascular and has minimal healing potential. Between the peripheral and white zones lies an intermediate zone, which has more limited healing potential.

Muscles and tendons

The primary extensor of the knee is the quadriceps, which consists of four muscles, namely, the rectus femoris, vastus medialis, vastus lateralis, and vastus intermedius. These muscles join together distally to form the quadriceps tendon, which inserts into the superior pole of the patella. Fibrous

Fig. 77.1 Sagittal section of the knee joint. ACL, anterior cruciate ligament; PCL, posterior cruciate ligament.

Fig. 77.2 Gross appearance of a right knee. ACL, anterior cruciate ligament; LCL, lateral collateral ligament; PCL, posterior cruciate ligament.

expansions from the vastus medialis and lateralis insert obliquely into the sides of the patella and form the medial and lateral patellar retinacula. The distal fibers of the vastus medialis, the vastus medialis obliquus (VMO), insert on the medial border of the patella and are the principal dynamic restraint to excessive lateral patellar subluxation. The hamstrings are the principal flexors of the knee. The semimembranosus and semitendinosus are located on the posteromedial and the biceps femoris on the posterolateral side of the knee. In addition to providing a degree of rotational stability, the hamstrings act as accessory stabilizers in the coronal and sagittal planes.

The iliotibial band (ITB) is a thickening of the fascia lata on the lateral aspect of the thigh. Proximally, the ITB is in continuity with the tensor fasciae latae muscle; distally, it inserts into the lateral femoral epicondyle and on Gerdy's tubercle. The ITB helps stabilize the lateral side of the knee and can act as an accessory extensor or flexor of the knee, depending on its position relative to the center of rotation of the knee.

Extensor mechanism

The extensor mechanism consists of the quadriceps tendon, the patellar tendon, and the patella. The Q angle is subtended by a line drawn from the

Fig. 77.3 Coronal magnetic resonance image demonstrating the medial collateral ligament (MCL) and menisci ligaments.

Fig. 77.4 Anatomic diagram of the quadriceps musculature with onlay of the Q angle.

anterior superior iliac spine to the center of the patella and another line drawn from the center of the patella to the tibial tubercle (Fig. 77.4). A normal knee Q angle measures approximately 13 degrees in men and 18 degrees in women, and an angle exceeding 20 degrees is abnormal. A high Q angle reflects a large unbalanced force vector tending to pull the patella laterally.

HISTORY, EXAMINATION, AND INVESTIGATION

History

The history of a patient's knee problem is a critical part of the assessment. Pain is the most common cause of referral to secondary care, and it is necessary to determine its nature. It should be established whether there is a continuous ache (e.g., arthritis) or a more intermittent mechanical component of the problem (e.g., meniscal tear). Closer review of the problem may identify a history of a new or long-established injury. Locking, catching, or giving way can occur. Patients may localize the pain to specific areas of the knee, although referred pain within the joint can be misleading in locating

pathology. Pain may also be referred from lumbar spine pathology or the hip joint. Previous medical history, including other joint disease and the patient's family history, can also offer critical information.

Examination

Examination of the knee should be performed by following the principles of look, feel, and move.

Observation

The knee examination begins with gaining adequate exposure of the knee, together with the joint above and below. Initially, alignment during standing should be noted, with the knee normally found in 4 to 7 degrees of valgus. Tibia vara is a common normal variant, but excessive varus or valgus alignment may reflect underlying knee pathology. The patient's gait and use of walking aids are then observed to look for typical patterns of gait that indicate knee pathology: antalgic, stiff knee and varus thrust. While standing, inspection of the soft tissues around the knee may reveal erythema, swelling, or scars. The patient is then further inspected on an examination couch. The quadriceps muscle is inspected, with a check for reduction in muscle bulk in comparison to the contralateral thigh. Muscle wasting is a key indicator of knee pathology.

Palpation

The integrity of the extensor mechanism is then assessed by asking the patient to actively straighten the knee against gravity. The ITB functions as an accessory knee extensor with the knee in an extended position and can hide significant disruption of the extensor mechanism. Active knee extension from a flexed starting position must therefore be assessed.

Active extension of the knee also allows assessment of patellofemoral crepitus and tracking. With one hand resting lightly on the patella, the knee is extended and flexed to ascertain patellofemoral crepitus. Patellar tracking is movement of the patella over the distal end of the femur and refers to engagement and articulation of patella within and out of the trochlear groove. In patients with a high Q angle or other causes of lateral patellar subluxation, the patella may translate laterally during the terminal 30 degrees of knee extension, which causes a "J" sign.

With the patient positioned supine the knee is examined for evidence of swelling or effusion. Subtle joint effusions may be detected by the "bulge test," in which fluid is milked into the suprapatellar pouch from the medial gutter with one hand and then the lateral side of the knee gently stroked in a proximal to distal direction to observe a bulge appear in the medial sulcus. Moderate-sized effusions may be detected by the "ballotement test," in which the examiner presses the patella down onto an extended knee while milking the suprapatellar pouch empty of fluid.

Palpation of the knee for tenderness should include the patella, quadriceps and patellar tendons, tibial tubercle, femoral epicondyles, collateral ligaments, hamstrings, pes anserinus, and ITB. Tenderness, swelling, or ecchymosis along these structures may indicate traumatic injury or rupture. The medial and lateral joint lines should be palpated for tenderness, and if present, provocative tests for meniscal pathology should be performed. Various tests have been described, but the principle is to elicit tenderness with rotatory movements of the tibia while the knee is taken through a range of motion. The popliteal fossa should be palpated to identify the popliteal pulse and any masses. A pulsatile and expansile mass in the popliteal fossa may indicate the presence of a popliteal aneurysm. In this scenario a bruit is heard on auscultation, and the mass should be further evaluated with an ultrasound scan.

Range of motion

Range of knee motion should be assessed next and comparison made between passive and active range. A normal knee moves within the range of 0 to 135 degrees, although considerable variation occurs. Up to 10 degrees of recurvatum (hyperextension), especially in younger patients, can be considered normal. Fixed flexion in which patients cannot fully extend the knee should be assessed. An extensor lag exists if asymmetry between active and passive extension of the knee is noted. This occurs after damage to or weakness of the extensor mechanism. The Q angle (see earlier) may be assessed with the patient supine and the knee flexed 15 degrees by identifying the anterior superior iliac spine, patella, and the tibial tubercle. The angle subtended by these lines is measured and recorded.

Ligamentous stability

Ligament abnormalities can be identified by performing a series of provocative tests that demonstrate inherent instability in the knee.

Fig. 77.5 Lachman test for anterior cruciate ligament injury.

The collateral ligaments are tested with the patient supine. A valgus force is applied across the knee with the knee initially in extension to test the MCL, medial capsule, posteromedial corner, and PCL. The test is repeated at 20 degrees of flexion to isolate the MCL and posteromedial capsule. If no endpoint is reached during the valgus stress, the MCL is deficient, but a firm endpoint suggests a strain or partial tear. A similar test on the LCL is performed by applying a varus force across the knee.

The ACL can be assessed with three tests. The Lachman test is the most reliable test for outpatient examination and has a high positive predictive value for detecting ACL injury. In the supine position the knee is flexed to 20 degrees. The examiner stabilizes the patient's thigh with one hand and grasps the proximal end of the tibia just below the joint line with the other hand. The femur is fixed with one hand by the examiner above the knee and an anterior translation stress is then applied across the knee by drawing the tibia forward with the other hand (Fig. 77.5). Laxity is recorded if abnormal translation is noted. The anterior drawer test is performed with the knee flexed 90 degrees. The examiner grasps the proximal end of the tibia with both hands and applies firm anterior translation stress while trying to detect abnormal anterior translation. With both these tests, hamstring activity can create a false-negative result. The pivot shift test is considered the "gold" standard test of ACL function. The examiner uses a combination of internal rotation and valgus stress applied across the knee during the range of movement from 0 to 40 degrees. A positive test produces a palpable clunk as the knee reduces from a subluxed position.

The PCL is assessed with the knees flexed to 90 and the heels placed together. The position of the tibial tubercles in the coronal plane is compared between knees, with discrepancy signaling PCL injury in the knee or the more posteriorly positioned tuberosity. This is known as a positive posterior sag test. Laxity in the PCL can then be confirmed by translating the tibia anteriorly relative to a fixed femur to reduce the sag. A positive posterior drawer test restores the tibia to the sagged position with posterior translation (Fig. 77.6).

Damage to the posterolateral corner can be identified by using the "dial test." With the patient supine and the knees initially flexed to 30 degrees, an external rotation stress is exerted (dialed) across the knee. A difference of greater than 10 degrees of rotational laxity is considered significant. The test is repeated with the knees flexed 90 degrees. Increased rotational laxity at 30 degrees but not at 90 degrees suggests an isolated injury to the posterolateral corner. However, laxity at both 30 and 90 degrees indicates combined disruption of the PCL and posterolateral corner (Fig. 77.7).

Patellofemoral joint stability

Patellar instability is assessed with the patella apprehension test. With the patient supine and the knee extended, a lateralizing force is applied to the patella while the knee is flexed from 0 to 20 degrees. A positive test is recorded when the patient is apprehensive of the action, usually stating that it makes the knee feel unstable.

Investigations

Radiologic investigation of a patient with a knee problem starts with weight-bearing anteroposterior, lateral, and skyline plain radiographs. Long-leg

Fig. 77.6 Posterior drawer test for tears of the posterior cruciate ligament.

Fig. 77.7 Dial test.

alignment films aid in assessment of the mechanical axis of the lower limb and are essential when considering reconstruction or osteotomy around the knee. Ultrasound scans are useful when investigating masses or tendon injuries, and the ability to perform this imaging test dynamically makes it valuable in patients with partial tendon ruptures. Computed tomography (CT) is excellent for assessing osseous anatomy, and three-dimensional CT reconstructions are increasingly being used in preoperative planning for treatment of intraarticular fractures. Magnetic resonance imaging (MRI) is the modality of choice for more detailed assessment of the knee. Any intraarticular pathology involving the soft tissues, bone marrow, ligaments, menisci, and articular cartilage can be detected with great accuracy.

SPECIFIC DISORDERS OF THE KNEE

Clinical problems within the knee joint can be considered in chronologic terms, with certain diagnoses being associated with specific patient age

groups (Table 77.1). Features of the clinical manifestation, investigation, and treatment of common knee conditions are summarized in the following sections.

Infancy and early childhood

Knee pain in an infant or toddler is uncommon but usually highly significant. A clear history may be difficult to establish, but painful swelling or limping must be investigated with some urgency to establish the cause, start treatment, and avoid disturbances in future growth. Infection must be considered, together with referred hip or spine pain. Subtle fractures may not be seen on radiographs, and nonaccidental injury must be excluded.

Referred hip pain

Hip pathology may produce ipsilateral knee pain as a result of the common sensory innervation of both regions by the obturator nerve. Common diagnoses such as Legg-Calvé-Perthes disease, slipped capital femoral epiphysis, transient synovitis, and septic arthritis may all be manifested in this manner. A careful history and examination of the hip are critical in making these diagnoses. Investigations play an important role, including blood tests¹ and imaging techniques.

Septic arthritis

Septic arthritis represents a surgical emergency in all age groups of patients, but the consequences of chondrolysis and secondary growth disturbance are particularly important for young patients. The etiology is usually hematogenous spread. Patients have pain, swelling, reduced movement, and systemic signs of infection. A dramatic increase in pain on passive joint movement is the key examination finding for septic arthritis. Joint aspiration, under ultrasound guidance if necessary, is mandatory, with samples sent for microbiologic investigation, including microscopy and culture. If the diagnosis is confirmed on investigation or strong clinical suspicion exists despite normal results of investigations, the joint should be washed out in the operating room via arthroscopic or open débridement and irrigation. Repeated surgical washouts may be required. Appropriate antibiotics, guided by culture sensitivity studies, are required for an extended period until the joint settles.

Osteomyelitis

Acute hematogenous osteomyelitis is the most common type of bone infection. It is usually seen in children and is more common in boys. The infection generally occurs in areas of high metabolic activity and commonly affects the distal femoral and proximal tibial metaphyses. Only 60% of patients are febrile on initial evaluation, but they typically have pain and local tenderness with raised inflammatory markers. Findings on plain radiographs are frequently normal, and changes such as periosteal reaction and bony destruction may take 2 weeks or longer to appear. MRI is the gold standard imaging technique and reveals early inflammatory change in bone marrow and soft tissues with hypointense signal on T1-weighted images and increased signal on T2-weighted series. Correct and timely diagnosis is crucial because delay and inappropriate treatment can result in the devastating complications of growth arrest and angular deformity. Antibiotic therapy is often sufficient for uncomplicated osteomyelitis, although surgery may be required in those with concurrent septic arthritis or abscess formation. The aim of surgery is to drain the abscess cavity and remove all nonviable and necrotic tissue.

Discoid meniscus

A discoid meniscus is a congenital anomaly of the knee found in 3% of the population (Fig. 77.8). It typically affects the lateral meniscus and may be found bilaterally in 20% of cases.² It results when the lateral meniscus does not differentiate into a semilunar shape and instead forms a thick wafer of fibrocartilaginous tissue. The anomaly in itself is asymptomatic; however, a tear in the meniscus can result in pain and mechanical symptoms in the affected knee. Discoid lateral menisci are classified as complete or incomplete (determined by coverage of the tibial plateau) and by Wrisberg type (determined by the presence or absence of the normal posterior meniscotibial attachment). Discoid menisci are more prone to tears because of the thickness of the meniscus, its diminished vascular blood supply, and in some instances, weak capsular attachment. Symptomatic tears may be treated by arthroscopic débridement and saucerization, but if the meniscus is unstable, it should be stabilized before partial meniscectomy.^{3,4}

Malignancy and hematologic conditions

Malignancies can first be manifested as arthritis caused by malignant cell infiltration of structures surrounding the joint. Patients are typically ill and may have difficulty using the affected limb. One or many joints can be

■ TABLE 77.1

Common causes of knee pain in different age groups

Age group	Intraarticular	Periarticular	Cause referred
Childhood (2-10 yr)	Juvenile chronic arthritis Osteochondritis dissecans Septic arthritis Torn discoid lateral meniscus	Osteomyelitis	Perthes disease Transient synovitis of the hip Septic hip arthritis Slipped capital femoral epiphysis
Adolescence (10-18 yr)	Osteochondritis dissecans Torn meniscus Anterior knee pain syndrome Patellar malalignment	Osgood-Schlatter disease Sinding-Larsen-Johansson syndrome Osteomyelitis Tumors	Slipped capital femoral epiphysis
Early adulthood (18-30 yr)	Torn meniscus Instability Anterior knee pain syndrome Inflammatory conditions	Overuse syndromes Bursitis	Rare
Adulthood (30-50 yr)	Degenerate meniscal tears Early degeneration after injury or meniscectomy Inflammatory arthropathies	Bursitis Tendinitis	Degenerative hip disease secondary to hip dysplasia or injury Lumbar herniated disk
Older age (>50 yr)	Osteoarthritis Inflammatory arthropathies	Bursitis Tendinitis	Osteoarthritis of the hip Lumbar spondylosis, stenosis

Fig. 77.8 Arthroscopic view of a discoid meniscus.

affected. Pathologic fractures associated with benign or malignant lesions may give rise to sudden disability and severe pain. A complete blood cell count, erythrocyte sedimentation rate, and radiographs are often the first step in making a diagnosis. Hematologic conditions can cause limb pain around the knee. Hemophilia is most commonly manifested as joint swelling secondary to hemorrhage. Knee hemarthrosis is most common, followed by elbow hemarthrosis. Children with sickle cell anemia may experience knee pain in the context of vasoocclusive sickle cell crises.

Inflammatory disease of the knee

Inflammatory conditions include juvenile rheumatoid arthritis (JRA) and pediatric spondyloarthritis. School-aged children and adolescents are most affected by polyarticular-onset JRA and type II pauciarticular arthritis. JRA has a wide spectrum of severity of symptoms ranging from mild pain and swelling with minimal limitation in activity to deforming and incapacitating symptoms. Long-term medical treatment may be required, depending on the type and severity of the arthritis. Early diagnosis and intervention are important to allow normal growth and development. Juvenile-onset spondyloarthritis (JSPAs) often affect boys at approximately 10 years of age and occur

at an estimated rate of 2 per 100,000 in the United States. JSPAs include the gastrointestinal-associated arthropathies, reactive arthritis, and psoriatic arthritis. JSPA may be manifested as an isolated arthritis, enthesitis, tendonitis, or dactylitis or as a clinical syndrome called seronegative enthesopathy and arthropathy. In the majority of children these syndromes will evolve into ankylosing spondylitis or another form of spondyloarthritis over the subsequent decades. These children will often have an asymmetric arthritis commonly involving the knee, midtarsal joint, and ankle. Spondyloarthritis should be suspected in those with a history of enthesitis affecting the Achilles tendon or insertion site of the plantar fascia to the os calcis.

Adolescence

Osgood-Schlatter disease

Osgood-Schlatter disease is a traction apophysitis of the tibial tubercle.^{5,6} It typically occurs during the adolescent growth spurt and is more common in boys. It results from repetitive tensile stress exerted by the pull of the quadriceps muscle, magnified by the patellar mechanism, on the insertion of the patella tendon into tibial tubercle apophysis. Patients classically report anterior knee pain that is exacerbated by jumping activities. Examination may reveal swelling or a prominent tubercle with localized tenderness. Pain is elicited with direct pressure and resisted knee extension. Plain radiographs frequently have normal findings in the early stages, but osseous fragments may be visible on lateral radiographs within the distal insertion of the patellar tendon in chronic cases (Fig. 77.9). Osgood-Schlatter disease is usually self-limited, with resolution of the symptoms after skeletal maturity. Treatment is therefore generally nonoperative and consists of modification of activity and physiotherapy with a focus on strengthening exercises and stretching of the quadriceps, hamstrings, and ITB. Occasionally, immobilization in a removable splint is required. One in 10 patients may eventually experience pain as an adult because of formation of a separate ossicle. Surgery is rarely necessary, but it may be indicated when osteochondral fragments cause persistent pain with kneeling.⁷

Sinding-Larsen-Johansson disease

Sinding-Larsen-Johansson disease is another traction apophysitis, similar to Osgood-Schlatter disease, that involves the distal pole of the patella.⁸ Pain and tenderness are felt at the distal pole of the patella, and the symptoms are aggravated by running, jumping, and kneeling. The natural history and treatment are similar to those described for Osgood-Schlatter disease.

Osteochondritis dissecans

Osteochondritis dissecans (OCD) is avascular necrosis of the subchondral bone with partial or complete separation of the bony fragment. Boys are affected three times more commonly than girls, with the peak incidence occurring in the second decade of life. OCD is generally unilateral, and the knee joint is by far the most commonly affected site. Within the knee, 80% of the lesions occur in the lateral border of the medial femoral condyle. Less common areas of involvement are the posterior aspect of the lateral femoral

condyle, the trochlea, and the patella. The exact cause is not fully understood but is thought to be multifactorial, with genetic predisposition, mechanical stress, and repetitive trauma contributing to development of the lesion. There is commonly a history of participation in sports with patients complaining of vague knee pain and swelling. Mechanical symptoms such as locking may be present when an osteochondral fragment is unstable or loose. Physical examination reveals an effusion with local tenderness over the OCD lesion. Plain knee radiographs are useful in delineating the OCD lesion or identifying osteochondral loose bodies. The tunnel view is especially good for detecting classic OCD lesions on the lateral aspect of the medial femoral condyle (Fig. 77.10). CT is helpful in identifying the precise

osseous extent of the lesion, but to assess the integrity of the overlying hyaline cartilage and to differentiate stable from unstable lesions, MRI, especially MR arthrography, is essential (Fig. 77.11).⁹

Treatment of OCD depends on the age of the patient and the severity of the lesion (Table 77.2, Fig. 77.12). Skeletally immature patients with stage 1 or 2 lesions have a favorable prognosis for spontaneous healing. Symptomatic patients are treated by limitation of activities, protected weight bearing, and gentle physiotherapy because motion of the knee joint contributes to nourishment of the cartilage. The prognosis is less favorable in skeletally mature patients, and conservative measures often fail to result in healing. The principles of operative management are maintenance of

Fig. 77.9 Osgood-Schlatter disease. Loose ossicles are present in the patellar tendon.

TABLE 77.2

Classification of osteochondritis dissecans (based on severity and arthroscopic appearance)

Classification	Appearance
Stage 1	Softening and irregularity of the articular cartilage without fissuring
Stage 2	Nondisplaced but breach of the articular cartilage
Stage 3	Displaced but attached <i>in situ</i> by intact fibrocartilage
Stage 4	Completely displaced osteochondral fragment

Fig. 77.10 Notch radiograph showing a lesion in the medial femoral condyle. An osteochondral defect developed in a 17-year-old with a defect over the weight-bearing area of the lateral femoral condyle.

Fig. 77.12 Arthroscopic view of an osteochondritis dissecans lesion in the medial femoral condyle.

articular congruity and removal of loose fragments. Stable lesions are treated by arthroscopic débridement and retrograde drilling to stimulate fibrocartilage formation. Unstable lesions require removal of small loose bodies and fixation of larger unstable osteochondral fragments with cannulated screws or bioabsorbable devices.

A variety of surgical techniques have been developed to address the difficult problem of large cartilage defects in young patients.¹⁰ Procedures such as microfracture and abrasion, in which the bony bed of the defect is débrided and drilled, are designed to stimulate fibrocartilage production by provoking an inflammatory reaction by local marrow cells. The resulting fibrocartilage lacks the tensile properties of hyaline cartilage, and it degenerates over time.¹¹ Osteochondral allograft or autograft transfer procedures involve harvesting osteochondral plugs from non-weight-bearing joint surfaces and reimplanting the plugs into an osteochondral defect in a weight-bearing area. Although good results have been demonstrated with this technique, the area that can be grafted is limited by the availability of donor site cartilage and by donor site morbidity. When allograft is used, a small risk for disease transmission is recognized.

A more recent development in cartilage repair surgery is autologous cartilage implantation (ACI). In this technique, the patient first undergoes diagnostic knee arthroscopy in which the size and location of the osteochondral defect are noted and a small, full-thickness sample of articular cartilage is harvested. From this sample, chondrocytes are isolated and cultured *ex vivo*. At least 6 weeks later, the patient returns to the operating room and cultured chondrocytes are implanted into the cartilage defect and sealed there with a periosteal patch or membrane via sutures or fibrin glue (Fig. 77.13). Encouraging outcomes have resulted from this procedure, and histologic evaluation shows stable repair tissue.¹²

Anterior cruciate ligament rupture

Isolated ACL ruptures are occurring with increasing frequency in children because of greater high-level sports participation. The controversy surrounding its management in skeletally immature patients has attracted much interest and debate in the literature over recent decades. The mechanism of injury and clinical features are similar to those in adults. ACL reconstruction in adults typically involves techniques for drilling bony tunnels, which if used in children would violate the physal plate. Traditionally, this has been thought to carry a potentially serious risk for growth disturbance.¹³ For this reason, extraphyseal methods of reconstruction have been developed for use in young children who require surgical stabilization to return to sports. Children who have no specific sports requirement and are not disabled by ACL laxity have historically been managed conservatively until skeletal maturity. There is now sufficient evidence to support the safe use of conventional transphyseal techniques in skeletally immature patients without any significant risk for growth abnormality.¹⁴⁻¹⁶

TABLE 77.3
Classification of chondromalacia patellae

Classification	Appearance
Stage 1	Softening and swelling of the articular cartilage
Stage 2	Deep fissures extending to subchondral bone
Stage 3	Fibrillation of the articular surface
Stage 4	Loss of articular cartilage with exposed subchondral bone

Adults

Anterior knee pain

Anterior knee pain can be caused by a wide range of conditions, including chondromalacia patellae, patellofemoral maltracking, and medial plica syndrome. A careful history should be obtained to establish the exact site of pain, as well as any exacerbating and relieving factors.¹⁷

Chondromalacia patellae

Chondromalacia patellae is sometimes referred to as patellofemoral syndrome¹⁸ and represents pathologic softening and fragmentation of the articular cartilage of the patella as a result of impact loading and excessive shear stress (Table 77.3). Patients with this condition commonly have anterior knee pain, especially on descending stairs and with prolonged sitting. Physical examination often reveals significant patellofemoral crepitation and retropatellar tenderness. In idiopathic cases the mainstay of treatment is physiotherapy with isometric quadriceps exercises and hamstring stretches. Patients with pain and mechanical symptoms may benefit from an arthroscopic procedure to remove any unstable chondral fragments. When associated patellofemoral malalignment is present, the underlying abnormality should be addressed to relieve the symptoms.

Patellofemoral maltracking, subluxation, and dislocation

Stability of the patellofemoral joint is derived partly from the osseous anatomy and partly from the muscles and ligaments around the patella. Instability often results from an imbalance between the medial and lateral forces acting on the patella and may be exacerbated by patella alta because a higher patella engages into the trochlear groove at a later point in the knee flexion arc.¹⁹ Static instability is associated with an abnormally high Q angle,

and dynamic instability may result from weakness of the VMO or contracture of the lateral retinaculum and ITB.

Patellofemoral instability may be characterized by patellar subluxation or dislocation. Patellar subluxations often reduce spontaneously and tend to be recurrent. Acute patellar dislocations may result from a direct blow to the knee and usually require medical assistance for reduction. The patella is always dislocated laterally, along with damage and tearing of the medial retinaculum. If the patella has spontaneously reduced, only swelling and tenderness may be noted over the torn medial retinaculum. Acute dislocation may be associated with an osteochondral fracture of the lateral femoral condyle or medial facet of the patella. In cases of recurrent dislocations, an underlying soft tissue or osseous abnormality is almost always present. The patient may have generalized ligamentous hyperlaxity, an abnormally high Q angle, patella alta, or a shallow trochlear groove. Chronic patellofemoral maltracking can cause a spectrum of symptoms ranging from pain to instability. Excessive lateral stress on the articular cartilage can result in anterior knee pain and, in the longer term, can cause arthritis. Patients may also complain of episodes of the knee “giving way” because of lateral subluxation of the patella. Physical examination may demonstrate a “J” sign, tight lateral retinacular structures, and a positive apprehension test.

Plain knee radiographs in patients with patellofemoral maltracking may reveal lateral placement of the patella, patella alta, hypoplasia of the distal femoral trochlea, or incongruity of the patellofemoral osseous anatomy. Patella alta is recognized on the lateral view by comparing the length of the patella with the length of the patellar tendon. The average ratio is approximately 1:1 (Fig. 77.14).¹⁹ Skyline views of the patellofemoral joint, taken with the knee flexed 30 degrees, may show the patella to be tilted laterally and translated toward the lateral femoral condyle (Fig. 77.15). Sclerosis may be seen in the subchondral bone of the lateral facet and is indicative of arthrosis from stress concentrated across the articulation. MRI can be particularly useful in assessing the integrity of the patellofemoral articular cartilage and measuring the tibial tuberosity–trochlear groove distance.

Treatment of patellofemoral maltracking varies according to the severity of symptoms. With an acute dislocation (Fig. 77.16) the patella must be reduced and the patient subsequently managed by mobilization as tolerated and physiotherapy for strengthening of the VMO and stretching of the ITB.

Fig. 77.14 Lateral knee radiograph with measurement of the Insall-Salvati ratio.

The decision-making process for operative intervention is complex; however, surgery is usually indicated for recalcitrant recurrent dislocations, for which the aim is to address the underlying abnormality and reduce the patient's risk for further chondral injury. Several surgical techniques have been described, including repair or reconstruction of the medial patellofemoral ligament, VMO advancement, lateral retinacular release, and tibial tubercle osteotomy.²⁰

Traumatic ligamentous injuries

Ligamentous injuries are common in young athletes. A ligament sprain is an injury in which the fibers are stretched or torn. In a first-degree sprain, the fibers are torn but function is unimpaired. In a second-degree sprain, more fibers are torn, along with stretching of the ligament, which causes abnormal joint laxity. A third-degree sprain involves complete ligament rupture with marked instability.²¹ The degree of instability after ligament injury is assessed by specific provocative maneuvers and quantified by using a three-point scale: I+ laxity is up to 5 mm, II+ is 5 to 10 mm, and III+ is 10 to 15 mm.

Anterior cruciate ligament injuries

ACL injuries are common in athletes engaging in sports requiring cutting, twisting, or jumping. Injuries are significantly more common in women, with female athletes being eight times more likely than male athletes to sustain ACL injuries.²² Potential risk factors include an increased Q angle, femoral anteversion, genu valgum, external tibial torsion, femoral intercondylar notch shape and size, ACL thickness, hormonal influences, and training techniques.

The classic history of an ACL injury involves a noncontact deceleration, jumping, or a pivoting action. It can also be caused by direct trauma such as a valgus force onto a flexed knee or hyperextension of an internally rotated tibia.²³ Patients typically describe a twisting injury with a backward fall and a palpable “pop” followed by knee pain and swelling. Resumption of activity is not usually possible, and walking is often difficult. The Lachman test is the most sensitive test for anterior tibial displacement and has 95% sensitivity. Radiographic studies may be useful but the findings are often normal. They may reveal a fracture of the tibial eminence—indicating avulsion of the tibial attachment of the ACL, or a Segond fracture (Fig. 77.17)—an avulsion fracture of the lateral capsule that is pathognomonic for ACL rupture.²⁴ MRI is the most useful diagnostic modality with a reported accuracy of greater than 95%. It is also a valuable screening tool for associated chondral and meniscal injuries. The overall incidence of meniscal tears in ACL injuries is reported to be as high as 70%, with the lateral meniscus more commonly being torn in the initial incident.²⁵ The risk for meniscal injury is somewhat static in the first few months following ACL rupture, but in the context of functional instability in an ACL-deficient knee, risk increases significantly with time after the initial injury.²⁶

Treatment of ACL injuries is patient specific and depends on the symptoms and the desired level of activity of the patient. Nonoperative treatment may be an appropriate option for a low-demand patient or one who is willing to make lifestyle changes and avoid activities that cause recurrent instability, and it should include an aggressive rehabilitation program and counseling about activity levels. However, in young patients, those with a desire to return to high-level sports, or patients with recurrent rotational instability, reconstruction of the ligament is recommended. Surgery involves secure fixation of the graft within bony tunnels in the femur and the proximal end of the tibia. The choice of graft is often surgeon dependent and includes synthetic graft, allograft, or autograft, with the patella and hamstring tendons being the two most commonly used grafts. Surgery is carried out once the knee is pain free and full range of motion is restored to allow immediate rehabilitation postoperatively.^{27,28} The success of surgery is largely dependent on the position of the tunnels and patient compliance with postoperative physiotherapy.

Fig. 77.15 Skyline radiograph showing lateral subluxation of the patella.

Fig. 77.16 Anteroposterior (a) and skyline (b) radiographs showing patellar dislocation.

Fig. 77.17 Anteroposterior radiograph of a Second fracture. The figure shows a flake of bone (arrow) and avulsion of the anterolateral capsule in the region of the Gerdy tubercle, frequently associated with rupture of the anterior cruciate ligament.

Posterior cruciate ligament injuries

PCL injuries occur much less commonly than ACL injuries, primarily because of the larger size of the PCL, which makes it biomechanically twice as strong as the ACL.²⁹ Typically, the injury occurs as a result of a direct impact against the anterior aspect of a flexed knee or a hyperextension injury resulting in an isolated avulsion or a combined ligament injury. Physical examination may reveal a contusion over the anterior aspect of the tibia with posterior tibial sag and a positive posterior drawer test result. An avulsion fracture of the tibial insertion of the PCL is sometimes visible on a lateral knee radiograph, although the findings on plain radiographs are often normal and the gold standard imaging modality is MRI (Fig. 77.18). Isolated rupture of the PCL does not usually result in significant functional knee instability unless other structures, especially the posterolateral corner, have also been damaged.^{30,31} Nonoperative treatment of isolated PCL injuries consists of short-term immobilization and protected weight bearing, followed by quadriceps-strengthening and range-of-motion exercises.

Medial collateral ligament injuries

The MCL is the major static stabilizer of the medial side of the knee joint. The vast majority of injuries to the MCL result from a valgus force, although an external rotational force sometimes leads to rupture of the posterior oblique ligament (POL) and posterior fibers of the MCL.³² Findings on

Fig. 77.18 Magnetic resonance image showing rupture of the posterior cruciate ligament (PCL).

physical examination include swelling, bruising, and tenderness along the course of the ligament. The knee must be examined in 20 to 30 degrees of flexion to isolate the MCL, as well as in full extension to determine whether other supporting structures such as the POL are injured, which signifies a much more extensive injury. Low-grade MCL tears are treated conservatively in a hinged knee brace to allow protected range of motion, followed by progressive physiotherapy.³³ There is a growing tendency to surgically repair high-grade MCL tears because nonoperative management of these injuries often results in an unsatisfactory outcome. Pellegrini-Stieda disease is an infrequent chronic sequela of an MCL injury in which a patient has persistent pain over the MCL femoral origin as a result of local calcification.

Fig. 77.19 Radiograph of a patient with Pellegrini-Stieda disease showing calcification of the insertion of the medial collateral ligament.

The area is tender to palpation, and pain is elicited on stressing of the ligament. Radiographs reveal characteristic calcification at the ligament insertion (Fig. 77.19). Treatment consists of rest and nonsteroidal antiinflammatory drugs (NSAIDs) because the condition is usually self-limited. Occasionally, targeted corticosteroid injection helps ameliorate the symptoms.

Lateral collateral ligament injuries

The LCL is the least commonly injured knee ligament in isolation. It is part of the posterolateral ligament complex of the knee, which also includes the lateral capsule, arcuate ligament, popliteofibular ligament, and popliteus tendon. Injury to the posterolateral structures frequently occurs in combination with injury to the cruciate ligaments and may represent a reduced knee dislocation. The mechanism of injury is typically a direct blow to the antero-medial aspect of an extended knee. In isolated LCL injury, the ligament usually ruptures at its fibular insertion, or it may avulse off the fibular styloid. Because of its close proximity to the common peroneal nerve, with severe injuries there is often some distal sensory and motor disturbance. Isolated low-grade injuries may be treated conservatively, but high-grade or combined injuries should be acutely reconstructed surgically.

Bursitis

Bursitis is inflammation of a synovial-lined bursa and may result from direct trauma, recurrent minor injury, infection, or crystal deposition diseases. The most frequent site of knee bursitis is the prepatellar bursa, which usually covers the lower half of the patella and the upper half of the patellar tendon. It can become chronically inflamed in those whose occupation involves much kneeling, thus giving rise to the eponym “housemaid’s knee.” Symptoms include erythema, swelling, and tenderness over the patella. Treatment of prepatellar bursitis depends on the underlying etiology but, as a general rule, involves rest, avoidance of kneeling, and systemic antiinflammatories. Occasionally, a large bursitis may be aspirated, and in cases of infective bursitis, parental followed by a course of oral antibiotics is often required. Surgical management is rarely indicated, although recalcitrant bursitis may necessitate open bursectomy.

Patellar tendonitis

Patellar tendonitis, also called “jumper’s knee,” is an overuse syndrome that occurs not uncommonly in young people participating in repetitive jumping sports such as volleyball and basketball. Chronic overloading of the tendon results in microtears, fraying, and focal degeneration of the deep fibers of the patellar tendon, especially near the insertion at the inferior pole of the patella.³⁴ Histologic evaluation reveals mucoid degeneration and fibroid necrosis. In older patients the superior pole of the patella may be affected

Fig. 77.20 Magnetic resonance image showing patellar tendonitis with high signal at the inferior pole of the patellar tendon.

by analogous quadriceps tendonitis. Symptoms include sharp localized pain at the apex of the patella exacerbated by activities that load the extensor mechanism. Findings on routine knee radiographs are usually normal, and MRI is the investigation of choice to confirm the diagnosis (Fig. 77.20). The tendon is weakened by this inflammatory response; however, tensile strength can recover if progressive stress is imposed on the tendon. The mainstay of treatment is therefore nonoperative management consisting of modification of activities, physiotherapy concentrating on eccentric loading exercises, and NSAIDs. A variety of braces and straps that stabilize the patella may be added to the physical therapy program. Surgery is reserved for recalcitrant cases; the degenerative tissue is excised to decompress the tendon, with a phased return to activities.

Iliotibial band syndrome

ITB syndrome is an overuse syndrome and the most common etiology of lateral knee pain in runners.³⁵ Several causes have been suggested, and the friction theory of repetitive ITB motion against the lateral femoral epicondyle during knee flexion and extension is most widely accepted.³⁶ Anatomic factors that biomechanically predispose patients to this condition include excessive genu varum, internal tibial torsion, planovalgus, and hip abductor weakness. Patients typically localize pain to the region of the distal ITB between the lateral femoral condyle and Gerdy’s tubercle and characteristically report worsening symptoms when running downhill or lengthening their stride. The mainstay of treatment is nonoperative: activity modification, NSAIDs, and physiotherapy for specific stretching exercises focused on the ITB, tensor fasciae latae, and gluteus medius. Injection of local anesthetic and steroid can aid in the diagnosis of ITB syndrome and may provide relief of pain in acute exacerbations. Surgery is reserved for recalcitrant cases that fail to improve with at least 6 months of conservative treatment.

Popliteal cysts

A popliteal cyst is a synovial fluid-filled mass located in the popliteal fossa. It is also referred to as a Baker cyst, who described it in 1877.³⁷ Popliteal cysts are generally considered to be distention of the bursa located beneath the medial head of the gastrocnemius muscle. This bursa directly communicates with the knee joint, and excess synovial fluid is forced into it via a one-way valve phenomena during knee flexion. Any underlying knee pathology causing accumulation of synovial fluid can result in the formation of a popliteal cyst, and degenerative joint disease is the most common cause of such cysts. Small cysts are frequently asymptomatic; however, patients

Fig. 77.21 Synovial chondromatosis.

TABLE 77.4

Milgram classification⁴¹

Phase 1 (early)	Active intrasynovial disease without loose bodies
Phase 2 (transitional)	Transitional lesions with OC nodules in the synovial membrane and OC bodies lying free in the joint cavity
Phase 3 (late)	Multiple free OC bodies with quiescent intrasynovial disease

OC, osteochondromatosis.

with larger cysts may have achy knee pain and a palpable posterior knee mass. Popliteal cysts, as with other synovial cysts, may enlarge or regress gradually over time, or they may rupture acutely. Plain radiography may confirm the underlying cause, and the mass is best evaluated with ultrasound or MRI. The differential diagnosis of a popliteal mass includes popliteal artery aneurysm, lipoma, nerve sheath tumor, and sarcoma. Treatment in adults is initially tailored to address the cause of the knee effusion.³⁸ Ultrasound-guided aspiration and corticosteroid injection may be performed to reduce synovial fluid volume and production. Surgery is indicated only in very rare cases when the cyst remains symptomatic and consists of cyst decompression and ablation of the communicating channel between the joint and cyst cavity, often via an open procedure.

Synovial chondromatosis

Synovial chondromatosis is a rare synovial proliferative disease of unknown origin.³⁹ It is characterized by cartilaginous metaplasia of the intimal layer of the synovial membrane of joints, tendons, and bursae (Fig. 77.21). The condition is most often seen in middle-aged men but has been reported in children and teenagers. The knee joint is most commonly affected, and involvement is typically monoarticular. Patients generally have pain and swelling⁴⁰ in the early stages, but multiple loose bodies can result in locking of the knee. In later stages of the disease, knee range of motion may be decreased, with calcified lesions clearly visible on plain radiographs. Knee stiffness may be caused by thickened metaplastic synovium and may portend a poor prognosis if severe. Treatment of symptomatic synovial chondromatosis involves arthroscopic removal of symptomatic loose bodies. In the first and second phases of disease (Table 77.4),⁴¹ active synovium should be excised. Recurrence is treated by repeated arthroscopic débridement.

Pigmented villonodular synovitis

Pigmented villonodular synovitis (PVNS), a rare, benign proliferative process, involves the synovial tissue, mainly of large joints. It was thought to be of a reactive inflammatory origin but is now regarded as a tumor of periarticular tissue. The knee is the most commonly affected joint. There is often a long history and delay in diagnosis. Patients typically complain of an intermittently painful knee and may have a history of recurrent atraumatic knee hemarthrosis with no underlying bleeding disorder. Aspiration of brown synovial fluid in the absence of recent trauma is characteristic and may often be the first indication of the disease. MRI is the mainstay for

Fig. 77.22 Magnetic resonance image of a knee with pigmented villonodular synovitis showing bony erosion.

imaging of PVNS and has a characteristic appearance because of the presence of hemosiderin (Fig. 77.22). The lesions have predominantly low signal intensity on T1- and T2-weighted images with marked enhancement on T1-weighted, contrast-enhanced studies. Treatment of PVNS depends on the extent and location (intraarticular or extraarticular) of the disease. Localized intraarticular PVNS may be successfully treated arthroscopically, but for diffuse PVNS, open synovectomy is now recommended to allow access to the posterior joint, collateral ligaments, and cruciate ligaments. Radiosynovectomy, or intraarticular injection of radioactive colloid, can be used as local adjuvant treatment following synovectomy. Radiation therapy can also be used as primary treatment of unresectable disease or as local adjuvant treatment.^{42,43}

Meniscal injuries

The menisci are the most commonly injured structure within the knee joint. In young adults, meniscal tears usually result from an acute traumatic or sports-related event and, in older patients, as part of a degenerative process. Meniscal injuries are also associated with chronic ligamentous instability. Tears are most frequently located in the midportion and posterior horn, with a higher proportion involving the medial meniscus. Patients typically have pain and swelling, and there may be mechanical symptoms of catching or locking. A locked knee will exhibit a springy block to extension, with pain occurring on forced extension. With an acute event it is crucial to establish the time interval during which the swelling developed. Effusion developing within 1 hour of injury signifies a hemarthrosis, which may result from peripheral tears involving the vascularized red zone, or signals a concomitant osteochondral fracture or a ligament rupture, most commonly the ACL. Plain radiographic findings are generally normal unless an associated osseous injury is present. MRI is the study of choice to confirm a meniscal tear, with diagnostic accuracy being greater than 90% (Fig. 77.23).⁴⁴ Treatment of meniscal tears depends on a multitude of factors, including age of the patient; pattern, size, and vascularity of the tear; general condition of the joint; and associated ligamentous injuries. The aim of treatment should be to preserve meniscal tissue wherever possible. Conservative management may therefore be appropriate for low-demand patients, chronic tears in a degenerative joint, radial tears smaller than 5 mm in length, partial-thickness tears, or stable longitudinal tears in the red zone.⁴⁵

In young patients with symptomatic tears, surgical intervention is indicated. When feasible, meniscal repair should be done in an attempt to maintain meniscal integrity and prevent the long-term degenerative changes that occur after meniscectomy. When meniscal repair cannot be done or is

Fig. 77.23 Magnetic resonance images of a degenerative medial meniscus tear in the coronal (a) and sagittal (b) views.

Fig. 77.24 Arthroscopic partial medial meniscectomy.

contraindicated, partial meniscectomy may be considered (Fig. 77.24), with the goal of retaining as much viable meniscal tissue as possible. Successful repair has been reported in more than 80% of cases in conjunction with ACL reconstruction, although success rates are lower for isolated repairs. Complications related to repair include neurologic injury, postoperative loss of motion, recurrence of the tear, and infection. Meniscal allograft transplantation may provide a treatment option when meniscus salvage is not possible or when total meniscectomy has previously been performed.

Extensor mechanism injuries

The extensor apparatus comprises the quadriceps tendon, the patella, and the patellar tendon. Disruption of this mechanism is one of the most common injuries in the elderly population. The injury often results from a simple fall in which the quadriceps muscle contracts forcefully and eccentrically against a flexed knee. Patients have an acutely painful, swollen knee

Fig. 77.25 Magnetic resonance image showing patellar tendon rupture.

with an inability to actively extend the knee. It should be noted that an intact straight leg raise does not exclude this injury because the ITB acts as an accessory extensor when the knee is fully extended. It is therefore important to assess active knee extension from a flexed position. Examination may reveal a palpable defect in the ruptured tendon. Lateral radiographs of the knee may demonstrate a fracture of the patella or patella alta when the patellar tendon is ruptured. MRI can be used (Fig. 77.25) in cases in which the diagnosis is uncertain; however, the investigation of choice is ultrasound, which is cheap and more readily available and allows dynamic assessment of the tendon. Treatment of complete rupture of the quadriceps

Fig. 77.26 Anteroposterior radiographs of total knee replacement (a) and unicompartmental knee replacement (b).

or patellar tendon consists of surgery to repair the extensor mechanism and physiotherapy for rehabilitation and restoration of function.

Isolated cartilage defects

The natural history of cartilage lesions in the knee is still unknown. Even though some lesions may be asymptomatic initially, it is widely held that they lead to degenerative arthritis of the knee over time. Treatment of these lesions is therefore important to prevent the development of osteoarthritis. Several surgical techniques have been used for the treatment of these lesions, with microfracture and ACI having the most favorable outcomes.⁴⁶ Microfracture is ideally suited for small, well-contained Outerbridge grade III/IV defects and has been reported to improve functional outcomes in more than 70% of patients. ACI is recommended for patients with larger or multiple defects and is intended to produce durable repair tissue that functions in a manner similar to hyaline cartilage. The future of biologic regenerative techniques for the treatment of articular cartilage defects in the knee is promising.

Osteoarthritis

Primary osteoarthritis is associated with aging and the “wear and tear” of life. It is a disease process and not part of the normal aging process. Secondary osteoarthritis, in contrast, tends to develop after a specific event, such as an infection or trauma. Any insult that alters the alignment, stability, or osseous congruence of the knee joint will accelerate the development of degenerative joint disease. It is therefore imperative to achieve anatomic

reduction of intraarticular fractures and the correct rotation and alignment of diaphyseal fractures and to restore ligamentous stability in the knee joint to minimize the risk for secondary osteoarthritis.

Medical or nonoperative management of osteoarthritis consists of a reduction in body weight by the use of regular low-impact aerobic exercise, physiotherapy, walking aids, and analgesia to control pain. Surgical management of knee osteoarthritis can be broadly divided into joint-preserving and joint-replacing (arthroplasty) procedures. Joint preservation procedures such as high tibial osteotomy aim to redistribute the weight-bearing forces to “offload” the degenerative compartment by realigning the mechanical axis of the lower limb. Ten-year survivorship rates with this type of intervention have been reported to be higher than 70%.⁴⁷

Knee arthroplasty, such as partial (unicompartment) or total knee replacement (TKA), is indicated for severe disability resulting from pain and deformity and should be considered only after adequate trials of conservative therapy (Fig. 77.26). The majority of patients undergoing knee arthroplasty achieve marked pain relief and improvement of function, although a small percentage continue to have pain, stiffness, or instability. In patients in whom osteoarthritis is isolated to one compartment, unicompartmental knee replacement (UKA) may be considered in those with an intact ACL, correctable deformity, and flexion greater than 90 degrees. UKA is technically a more challenging procedure but has gained popularity in carefully selected cases because of its distinct advantages over TKA, which include lower perioperative morbidity and blood loss, preservation of bone stock, more normal knee kinematics, and accelerated patient recovery.⁴⁸⁻⁵⁰

The ankle and foot

■ ANTHONY C. REDMOND

- Problems affecting the foot and ankle are common in rheumatology practice but are often neglected.
- Foot problems require consideration of local mechanical demands as well as systemic disease processes.
- A simple but comprehensive clinical assessment of the ankle and foot can be performed in around 1 minute.
- Many rheumatologic problems affecting the ankle and foot can be self-managed by the patient.
- Foot problems can be complex in people with systemic rheumatologic disorders and often require onward referral and/or appropriate multidisciplinary care.

INTRODUCTION

Recent years have seen some significant advances in the care of foot and ankle problems. In this chapter the manifestations of foot abnormalities are covered for the major rheumatologic disorders: rheumatoid arthritis, osteoarthritis, the seronegative arthritides, connective tissue disease, crystal diseases, and miscellaneous conditions including hypermobility syndrome. The principles of assessing and treating foot and ankle problems in rheumatology are covered, along with the relevant specific approaches.

EPIDEMIOLOGY OF FOOT AND ANKLE PROBLEMS

Approximately 10% of all adults report significant foot pain at any given time, and the number increases with age so that half of individuals older than age 50 have foot pain.^{1,2} Foot problems are also five times more common in females than in males. When ankle and foot problems are present there is the potential for significant impact because the involvement of such important weight-bearing structures leads to compromise of daily activities.^{3,4} Furthermore, foot problems rarely occur in isolation and are often found in conjunction with other musculoskeletal problems such as hip or knee pain.⁵ Despite the high prevalence of foot symptoms in patients coming to rheumatology clinics, foot and ankle problems are relatively neglected. Time constraints are often blamed, and poor training or limited confidence in the clinical examination of foot problems may contribute.⁶ However, the prevalence of foot problems in rheumatology is high enough that an explicit question about foot problems, and (when relevant) a basic screening examination, should be considered an integral part of every patient encounter in rheumatology practice.

**ANATOMY OF THE ANKLE AND FOOT****EXAMINATION OF THE FOOT AND ANKLE**

A basic ankle and foot screen need take no more than 1 minute per foot provided it is performed by an assessor with the requisite knowledge, training, and practice. A good starting point for lower limb assessment is the

Regional Examination of the Musculoskeletal System (REMS).⁶ For a more detailed foot examination, the author and colleagues have described extensively a Leeds foot assessment protocol that is a comprehensive assessment of foot problems based on the widely used approach of history→observation→examination. A detailed development of this approach can be found elsewhere.⁷

In routine practice, the most logical overview of foot and ankle involvement is provided by a simple assessment of the patient walking, followed by observation of the legs and feet with the patient standing still, followed by observations with the patient seated or lying supine (i.e., not weight bearing). It is helpful to observe the transition between non-weight bearing and weight bearing to note any changes that occur as the limb accepts weight.

Once the examination moves on to the specific exploration of ankle and foot abnormalities, it is useful to conduct a systematic observation of the overall foot shape and palpation of the relevant joint margins (ankle, subtalar, midfoot joints, and metatarsophalangeal [MTP] joints), soft tissue structures, and insertions to isolate inflamed or damaged tissues. Active movement of the ankle is evaluated, with assessment of the direction, range, and quality of motion and noting of any related pain. Finally, the assessment is completed with clinician-mediated passive motions of the ankle, subtalar, midfoot, and forefoot joints, with pain and the direction, range, and quality of movement again noted. Using a 1-minute protocol it is possible to identify the soft tissue structures involved, differentiate ankle involvement from subtalar disease, identify midfoot disease, and isolate and quantify forefoot joint involvement.

IMAGING

Traditionally, the most widely used imaging modality has been plain radiography, although it is limited to the assessment of existing bony anatomy and joint damage. Foot radiographs can be taken either non-weight bearing—the norm in most centers—or, increasingly, with the patient bearing weight. When available, weight-bearing radiographs better represent the foot in its functional state and allow monitoring of postural change over time.

Other imaging modalities useful in the assessment of foot and ankle problems are magnetic resonance imaging (MRI), ultrasonography, computed tomography, and scintigraphy.⁸ These modalities are used less often than plain radiography because of cost and access but can provide useful diagnostic information, particularly about the soft tissues (Table 78.1). Scintigraphy, which was used widely in the past in the diagnosis of foot stress fractures, has largely been superseded by MRI, although expertise in interpretation of MRI imaging of the complex anatomy of the foot may not be available in all units. Ultrasonography can be very useful in imaging foot problems and is used increasingly in rheumatology. The high resolution afforded by ultrasonography can be useful in identifying precisely which tissues are associated with presenting symptoms. Features such as power Doppler also enable differentiation between active inflammation and non-inflammatory or mechanical disorders.⁸

OTHER ASSESSMENTS

Recent advances in the technologies available to quantify foot function in health and disease have made diagnosis of the various systems increasingly feasible. Using affordable hand-held Doppler ultrasonography or photoplethysmography units, vascular pathologic conditions can be quantified accurately, and neurologic status can be assessed using monofilaments or

The ankle is a simple mortise that articulates with the talus inferiorly. The motion of the ankle is almost entirely plantar flexion/dorsiflexion. Conversely, the foot is a complex structure consisting of 26 bones (Fig. e78.1) and more than 30 articulations. For simplicity the foot can be simplified into three interrelated functional units: the hindfoot/ankle (consisting of the ankle, talus, and calcaneus), the midfoot (talus/navicular/cuneiforms and cuboid), and the forefoot (metatarsals and associated digits). The main roles of the foot and ankle are to provide a stable platform for locomotion and to facilitate progression of the leg over the fixed foot. The functional units of the foot are interrelated, and so the stability of the distal regions (i.e., the midfoot and forefoot) is affected by the regions proximal to them and vice versa. During normal locomotion the healthy foot goes through a repeated cycle of pronation and supination. In early stance physiologic pronation facilitates adaptation to uneven surfaces and shock absorption, and a subsequent period of resupination provides a more rigid lever for propulsion and a resulting conservation of energy. In association with some conditions, the pronation/supination cycle may be impaired; this results in overpronation (foot flattening), which leads to instability and excessive weight bearing in the medial structures, or oversupination (often seen as a cavus/cavoid foot type), which leads to excessive rigidity and poor shock absorption combined with a lateral deviation in the path of the center of mass. Change in the load distribution can lead to localized increases in pressures under the forefoot (and to a lesser extent the midfoot and hindfoot), causing joint pain, soft tissue change such as bursitis, or skin change such as clavus (corn) or hyperkeratosis (callus) formation. These are all common secondary features of rheumatologic conditions.

Ankle

The ankle is a hinge joint composed of the distal end of the tibia and fibula and the talar dome (Fig. e78.2). The talus is stabilized in the mortise by the medial and lateral malleoli. The strength of the ankle joint is augmented by the deltoid ligament medially and three ligaments laterally: the posterior talofibular, calcaneofibular, and anterior talofibular ligaments, which are

often injured in ankle sprains. Syndesmotic ligaments stabilize the fibula to the tibia, permitting a few degrees of rotation and a few millimeters of translation.

Tendons passing around the ankle are held in place by a series of extensor and flexor retinacula (Figs. e78.3 and e78.4). Within a few centimeters of the retinacula the tendons are invested in a synovial sheath, which can become inflamed and lead to tenosynovitis. The tendons pass around the ankle, along with a neurovascular bundle, in three compartments; the anterior, the posteromedial, and the posterolateral. Several mnemonics have been developed to help clinicians recall the relative positions of the anatomic structures within the compartments. For the anterior compartment, from medial to lateral, a useful mnemonic is *Tom Hates Dick*, representing the tibialis anterior, extensor hallucis longus, and extensor digitorum longus (Fig. e78.5). Extensor tendons cross the anterior aspect of the ankle extending from the anterior compartment of the leg distally to their insertion on the foot. The extensor tendons tibialis anterior, extensor hallucis, and extensor digitorum longus are stabilized by a superior and an inferior retinaculum, and their main function is to dorsiflex the ankle and toes.

In the posteromedial compartment the mnemonic *Tom, Dick and (A Very Nervous) Harry* applies representing, from the medial malleolus to the Achilles tendon, the tibialis posterior, flexor digitorum longus, (posterior tibial artery, tibial vein, tibial nerve), and flexor hallucis longus. Hugging the medial malleolus, the posterior tibial tendon is the most medial and anterior, followed in the posterior direction by the flexor digitorum longus, posterior tibial artery and veins, posterior tibial nerve, and flexor hallucis longus (FHL) (see Fig. e78.3). The low-lying muscle of the FHL is closely apposed to the posterior tibia, and its tendon runs in a tight sheath directly behind the talus and between the posterior lateral and posterior medial tubercles. The relationship is so close that often subtalar or ankle synovitis tracks along the FHL tendon sheath. The flexor retinaculum, the “roof” of the tarsal tunnel, encases the posterior medial tendons and is anchored from the medial malleolus to the calcaneus. The posterior tibial tendon, perhaps the most structurally critical of the medial tendons, provides support for a neutral heel position, prevents arch collapse secondary to gravity (the main result being flatfoot acquired in adulthood), provides critical push off during ambulation, and controls inversion of the subtalar joint through its insertion on the navicular.

The peroneus longus and brevis are located in the lateral compartment of the lower leg, and their tendons travel posterior to the fibular and lateral malleolus (see Figs. e78.2 and e78.5). They are found in a single tenosynovial sheath and are also stabilized by the superior and inferior retinacula. Their primary role is as evertor stabilizers of the foot and ankle.

On the posterior aspect of the ankle, the gastrocnemius and soleus tendon complex (Achilles tendon) inserts into the posterior surface of the calcaneus (see Fig. e78.3). There is no specific tenosynovial sheath encasing

the Achilles tendon, but it is surrounded by a paratenon as well as superficial and deep bursae. The deep retrocalcaneal bursa is found between the Achilles tendon insertion and the posterior calcaneus and serves to decrease friction between the tendon and bone. The superficial (retro-achilleal) bursa is the adventitial bursa, which is located between the skin and the paratenon to provide protection (Fig. e78.6). The gastrocnemius-soleus complex through the Achilles tendon provides powerful plantar flexion, resistance to gravity during standing, transition from a seated position to upright, forward propulsion of the legs during gait, stair climbing, and jumping. The movements of the ankle include dorsiflexion and plantar flexion with the axis of movement generated approximately between the tips of the malleoli. Normal passive range of motion of the ankle is 10 to 25 degrees of dorsiflexion and 40 to 50 degrees of plantar flexion.

Foot

As noted earlier, the foot can be divided into three functional units: hindfoot, midfoot, and forefoot (see Fig. e78.1). The main articulation of the hindfoot is the subtalar joint (talus and calcaneus), which is a complex three-facet joint responsible for inversion/eversion and pronation/supination of the foot. The talus sits on the calcaneus on the superior surface of the sustentaculum tali, which provides stability and a point of routing for the posteromedial soft tissues. The normal passive motion of the hindfoot is 20 to 30 degrees of total excursion, usually with more inversion than eversion available.

The midfoot bones consist of the navicular, cuboid, and three cuneiforms and functionally include the talonavicular, calcaneocuboid and tarsometatarsal (TMT) joints (see Fig. e78.1). These joints permit plantar flexion/

Fig. e78.5 Tendons around the ankle. dorsiflexion and rotation and serve functionally as a limited composite ball-and-socket joint, allowing adjustments to uneven terrain and dynamic distribution of forces in the midfoot during normal walking.

The forefoot extends from distal to the TMT joints and includes the metatarsals and phalanges (see Fig. e78.1). Each metatarsophalangeal (MTP) joint has its own synovially lined capsule, supported by medial and lateral collateral and plantar ligaments. Forefoot motion includes dorsiflexion and plantar flexion as well as pronation and supination as influenced by the hindfoot. The first MTP joint accommodates 70 to 80 degrees of dorsiflexion and 40 to 50 degrees of plantar flexion. Approximately 30 degrees of dorsiflexion is required for normal walking. The interphalangeal joints in the toes are hinge joints that allow plantar flexion and dorsiflexion. These joints are flexed by the FHL and flexor digitorum longus muscles through their plantar tendon insertions and extended through the extensor hallucis longus and extensor digitorum longus through their dorsal insertions.

Fig. e78.6 Bursae around the ankle.

■ TABLE 78.1

Differential diagnosis of ankle and foot pain

Anterior ankle	Anterior impingement Ankle arthritis/synovitis Osteochondral defect/lesion (cartilage injury) Loose body within the joint Talar avascular necrosis Talar stress fracture Tenosynovitis of the extensor hallucis longus, extensor digitorum longus Deep (central) or superficial (anterolateral) peroneal nerve injury Saphenous (anteromedial) nerve injury
Posterior ankle	Os trigonum (accessory ossicle involving the posterior lateral tubercle of the talus) Posterior impingement Retrocalcaneal bursitis Achilles tendinopathy Flexor hallucis longus tendinopathy or stenosis
Posterolateral ankle	Peroneal tendinopathy Subfibular impingement due to flatfoot and impingement Fibular stress fracture Sural nerve injury Lateral ligament injury (sprain)
Posteromedial ankle	Posterior tibial tendinopathy Flexor digitorum longus/flexor hallucis longus tendinopathy Tibial stress fracture Medial malleolar stress fracture Tarsal tunnel syndrome Tibial nerve injury Deltoid ligament injury
Heel	Achilles insertional tendinopathy Inflammatory enthesitis Plantar fasciitis Haglund disease (pump bump) Calcaneal stress fracture
Hindfoot	Subtalar, talonavicular, or calcaneocuboid arthritis/synovitis Posterior tibial tendon dysfunction/tendinopathy (medial) or peroneal tendon dysfunction (lateral) Occult fracture of talus, calcaneus cuboid, or navicular Accessory navicular
Midfoot	Insertional tendinopathy (peroneal, posterior tibial, tibialis anterior) Arthritis/synovitis (navicular-cuneiform, cuneiform-metatarsal, cuboid-metatarsal) Navicular stress fracture Spring ligament strain
Forefoot	
First ray, first MTP joint, hallux	Arthritis/synovitis MTP (hallux limitus/rigidus) and IP joints Hallux valgus Hallux varus Sesamoiditis Gouty monoarthritis
Second to fifth rays, MTP joints, lesser toes	Arthritis/synovitis (MTP, proximal and distal IP joints) Lesser toe deformities (hammer and claw toes) Metatarsalgia MTP instability MTP dislocations Morton neuroma (interdigital neuralgia) Stress fracture of the metatarsals Bunionette (fifth metatarsal phalangeal deviation) Rheumatoid nodules Bursitis (intermetatarsal or adventitious) Ulcer Infection

IP, interphalangeal; MTP, metatarsophalangeal.

BOX 78.1 OTTAWA RULES FOR REFERRAL FOR RADIOGRAPHY IN THE PRESENCE OF ANKLE SPRAIN

Radiographic investigation is required if there is pain in the malleolar zone and any one of the following is present:

- Bone tenderness along the distal 6 cm of the posterior edge of the tibia or tip of the medial malleolus, *or*
- Bone tenderness along the distal 6 cm of the posterior edge of the fibula or tip of the lateral malleolus, *or*
- An inability to bear weight both immediately and at the clinic for four steps.

vibration perception meters. Assessment of musculoskeletal function has also improved enormously, and technologies exist that can quantify activity profiles, overall functional ability, the motions and forces occurring in specific joints, and the forces and pressures underneath the feet. Most of these technologies are expensive and time consuming to use, however, and although they are common in research settings they offer less advantage in day-to-day clinical practice over keen observation and clinical experience.

LOCAL ANKLE AND FOOT PROBLEMS

Ankle sprains

Acute ankle injuries rarely are encountered in rheumatology practice, but care must be taken to ensure that severe soft tissue injuries and fractures are recognized. The most common site of ankle sprain is the lateral ankle. The Ottawa ankle rules for requiring radiography are a useful triage tool (Box 78.1).

Chronic ankle instability after a severe ankle sprain can lead to osteochondral defects in the articular surface of the talus and the tibia. If ankle pain becomes chronic following sprain injury, then ligament rupture, osteochondral lesions, or avulsion injury (at the base of the fifth metatarsal) should be considered. In these cases further imaging diagnostics are required. Nonsurgical treatment of chronic ankle instability requires strengthening the peroneal muscles and improving proprioception. Bracing or taping can help, particularly when used during activities in which there is a risk of further ankle sprain. If there is no response to nonsurgical treatments, referral for surgical evaluation with a view to stabilization may be necessary.

Impingement syndromes

Anterior ankle impingement is most often associated with repeated dorsiflexion (common in ballet and ball sports) and direct microtrauma (particularly seen in soccer players during kicking), which causes damage at the anteromedial margins of the articular cartilage. Anterior tibiotalar spurs create a bony mass (Fig. 78.1) that leads to the clinical features of anterior ankle pain and a reported feeling of blocking of dorsiflexion. Lateral-view conventional radiographs can explore the presence and extent of osseous spurs, which occur at the anterior and medial articular margins. Conservative management is often of limited help, and surgical or arthroscopic resection of the osseous spurs may be required.

Anterolateral impingement can develop secondarily to a relatively minor injury if ongoing functional instability leads to further soft tissue hemorrhage, synovial scarring, and hypertrophy. Anterolateral ankle pain will be provoked by supination or pronation of the foot. If the abnormality is focal, then symptomatic relief can be obtained with steroid injections into the thickened capsule or nodules combined with physical therapies.

Posterior impingement develops in response to repeated or forced ankle plantar flexion and compression of tissues between the posterior calcaneus and tibia (Fig. 78.2). The lateral talar process or an os trigonum (an unsupplied secondary ossification center) can also increase the degree of soft tissue compression with or without stress reaction in the bone itself. The soft tissues compressed include the Kager fat pad, the tibiotalar joint capsule, and local ligaments. Posterior impingement is typically chronic and of insidious onset, affecting athletes who regularly undergo forced plantar flexion. Symptoms include posterior ankle pain exacerbated by either dorsiflexion or plantar flexion, and on examination there is posterior tibiotalar joint tenderness not involving the Achilles tendon. Conventional radiographs can demonstrate minor bony changes, but the same findings are often seen in asymptomatic individuals. MRI is preferred because it can define bone marrow edema, fracture lines, or active bony impingement.

Achilles tendinopathy

The Achilles tendon can be affected by traumatic or degenerative damage, typically at the myotendinous junction or the insertion into the calcaneus. Note that the Achilles tendon has no synovial sheath, so tenosynovitis cannot occur. Risk factors for chronic Achilles tendinosis include previous injury and older age, and the tendon can be damaged by repetitive micro-trauma or an acute injury. Full-thickness tears are obvious on clinical examination and require immediate surgical intervention. A partial tear or pathologic thickening of the tendon can occur in the substance, proximal to the insertion where the blood supply is poorest. A fusiform swelling may be palpable and can be confirmed by MRI or ultrasonography (Fig. 78.3). Conservative treatment of Achilles tendinopathy is difficult and somewhat controversial. The treatment algorithm proposed by Alfredson and Cook,⁹ involving heel drop stretches, glyceryl trinitrate patches, and sclerosing treatments, may offer some advance over traditional approaches.

Tibialis posterior tendon dysfunction and acquired adult flatfoot

Tibialis posterior dysfunction (TPD) is a progressive tendinopathy of the tendon of the tibialis posterior muscle that can result in an acquired flatfoot in older adults. Initial symptoms are pain and swelling in the medial ankle, and sometimes there is concern over the changing shape of the foot as the arch flattens. As the pathologic process progresses the foot acquires a marked and progressively valgus position. A useful diagnostic test is to ask the patient to stand on tiptoe using only the affected side. In the presence of

tibialis posterior dysfunction, this is not possible unless the patient is counterbalanced by the contralateral limb. Diagnosis can be confirmed with ultrasonography or MRI, and early, conservative treatment employs various combinations of orthoses, supportive footwear, ankle taping, and bracing to offload the tendon and support the midfoot. Surgical treatment includes tendon transfer if the tendon has adequate structural integrity, combined with hindfoot osteotomy. In severe cases reconstruction and arthrodesis of the hindfoot is required.

Flatfeet (pes planus) and high arched feet (pes cavus)

The range of naturally occurring foot postures comprises a continuum from cavoid (or highly arched), through obviously normal, to flat (or planus). At the extremes of this continuum are features that are clearly pathologic (such as the frank cavus foot of inherited neuropathy or the planovalgus foot of established rheumatoid arthritis). Between these extremes, however, although that abnormal foot posture can increase mechanical loads on local structures and so may predispose to mechanical foot pain, care must be exercised to avoid medicalizing normal variants. There is insufficient evidence to support active intervention in most cases of asymptomatic flatfoot, and therapy should be directed at the combination of any presenting symptoms and the underlying biomechanics. Mechanical therapies can include footwear modifications, foot orthoses, taping, splints, and braces. The goal of most mechanically mediated treatments for the mobile flatfoot is to limit excessive mobility of affected joints and to promote stability. Conversely, treatment for the rigid cavoid foot is aimed at improving shock absorbency and stretching any tight soft tissues. Useful treatment approaches for cavoid feet include cushioning insoles, change in footwear, and stretching exercises.

Nerve entrapments

Rheumatology patients present with symptoms of nerve entrapment because of the complex anatomy and high prevalence of osteophytes and altered bony structures in this group. The most common nerve entrapment syndrome in the foot is so-called Morton neuroma, which is not a true neuroma but a fibrotic enlargement of the perineurium that affects the plantar digital nerve just proximal to the metatarsal heads. It is usually seen in the third and fourth metatarsal space but can occur in any of the intermetatarsal spaces.

The typical clinical presentation is of pain, numbness, or tingling in the affected interdigital cleft and the associated toes that may radiate proximally or onto the plantar aspect of the forefoot. Tight footwear and high-heeled shoes exacerbate the symptoms, and the clinical diagnosis can be aided by squeezing the forefoot across the metatarsals while exerting a pressure between the MTP joints of the affected area to reproduce symptoms. A Mulder click, which can be elicited by lateral compression, was considered diagnostic although the click can be elicited in normal feet. Differentiation of Morton neuroma and intermetatarsal bursitis can be made readily with ultrasonography or MRI. Treatment may include advice to adopt wider-fitting shoes, use of orthoses, local steroid injection, or oral nonsteroidal antiinflammatory drugs (NSAIDs). Surgery may be required in severe cases.

Tarsal tunnel syndrome is the other significant nerve entrapment found in rheumatology practice and involves the tibial nerve, which is compressed as it passes around the posterior medial aspect of the ankle. Tarsal tunnel syndrome may be caused by compression arising from tendinopathy or tenosynovitis or may be secondary to a severe valgus position of the ankle, such as can occur in rheumatoid arthritis. The symptoms include numbness, tingling, and pain in the arch area, which can radiate to the plantar surface and medial aspect of the ankle. Clinical diagnosis can be made by percussion to elicit the Tinel sign. When local inflammation underlies the compression, local injection of steroid may be helpful. When the cause is a valgus heel position, short-term reduction of symptoms can sometimes be achieved by splinting, taping, or orthoses; otherwise, surgical intervention may be required.

Heel pain

Some 10% of people will experience an episode of plantar heel pain at some point in their lives, and heel pain is more common in rheumatology patients. Plantar fasciitis is the most common underlying pathologic condition, characterized by thickening of the plantar fascia at the enthesis of the calcaneal tubercle and in some cases extending along the fascia (Fig. 78.4). The characteristic symptom is pain on the plantar surface of the heel (sometimes extending into the medial arch) during activity or on initial weight bearing.

Fig. 78.3 Sonograms of Achilles tendon showing (a) normal structure and (b) fusiform swelling indicating tendinopathy (with power Doppler ultrasonographic evidence of increased vascularity). (From Conaghan PG, O'Connor P, Isenberg D, editors. *Musculoskeletal imaging*. Oxford specialist handbooks in radiology. Oxford: Oxford University Press; 2010. With permission.)

Ultrasonography can be useful in confirming the presence of fascial thickening. Many cases are self-limiting, and in any case self-care is the best initial option. Recommending change of footwear and encouraging weight loss is often helpful, and physical therapies such as stretches can provide additional benefit. There is some evidence of efficacy for taping¹⁰ and the use of contoured foot orthoses.¹¹ There is also evidence for the short-term benefit of injection with a corticosteroid, although the injections are painful and the long-term benefits unclear.¹²

Posterior heel pain can be caused by Achilles tendon enthesitis, which is common in seronegative arthropathies, or by bursitis in one of two sites. The retrocalcaneal bursa is an anatomic bursa that lies deep to the Achilles tendon, and the Achilles bursa is an adventitious bursa that is superficial to the tendon insertion but is not always present. The Achilles bursa is especially prone to mechanical irritation from footwear. Bursitis arising in the deeper, retrocalcaneal bursa is more often associated with inflammatory disease such as rheumatoid arthritis. MRI or ultrasonography is diagnostic.

Treatment of local, mechanical bursitis centers on physical therapies and use of NSAIDs. Modification of footwear can help prevent further irritation. Bursitis associated with inflammatory disease usually responds to corticosteroid injection.

Midfoot pain

Plantar midfoot pain usually originates in the soft tissues and is part of the presentation of plantar fasciitis and related conditions. Dorsal midfoot pain of insidious onset more commonly implies degenerative change¹³ or bony damage such as mechanical stress reactions. There is currently little evidence of benefit of any specific treatment approaches for midfoot osteoarthritis, and NSAID use plus mechanical therapies are the best available option.

Stress reactions and stress fractures can arise at sites of high mechanical demand. The navicular and the metatarsals are the most common sites of stress fracture, although diagnosis can be difficult because the fractures often are not visible on plain radiographs, especially in the early stages. A stress reaction or fracture is characterized by diffuse pain in the midfoot, with exacerbation on activity and increase in intensity and localization of pain. The onset usually follows an increase in activity levels such as sports participation (e.g., distance running) or long walks, although stress reactions can be precipitated by relatively normal levels of activity in patients with poor bone stock.

Any fracture is usually preceded by profound bony edema. Scintigraphy has traditionally been used to identify early stress reaction and MRI is also highly sensitive to stress fractures. Treatment is with local offloading and systemic antiresorptive agents.

Forefoot pain

In the absence of systemic disease, most forefoot pain is relatively benign and associated with local mechanical demands. High pressures can occur

under the plantar MTP joints when clawing or subluxation of the toes or loss of fat pad protection inhibits the normal distribution of loads. There may be musculoskeletal discomfort and associated thickening of the skin, (hyperkeratosis/callus and clavus/corn formation). Some common causes of pain in the forefoot have been described previously (e.g., Morton neuroma), and although intermetatarsal bursitis is a common manifestation of inflammatory arthritis it can also be seen in otherwise healthy individuals.

RHEUMATOID ARTHRITIS

The ankle joint is affected in only 10% to 20% of people with rheumatoid arthritis (RA), but because of the many synovial structures in the foot, about 80% to 90% of people with RA have foot involvement.¹⁴ The foot is involved even in early disease,¹⁵ and the initial onset of RA is noted in the foot almost as frequently as in the hands. The forefoot is affected in more than three quarters of people with RA and the hindfoot (subtalar joint) is involved in around two thirds of those with longstanding RA.¹⁶ The prevalence and impact of foot problems is closely related to disease duration,¹⁴ and overall foot-related impact arises from a combination of factors, including pain, inflammation, and altered mechanics. Foot involvement contributes to difficulty in walking in about three quarters of people with RA and is the main or only cause of walking impairment in one quarter.¹⁴

Articular damage is driven mainly by synovitis but in the ankle and foot this is compounded by the mechanical stress of weight bearing. In the longer term irreversible changes occur in the anatomic structures, including valgus deformity of the heel, forefoot changes, flattening of the arch (Fig. 78.5), and typical forefoot hallux valgus-type presentation¹⁷ (Fig. 78.6). Although better disease-modifying antirheumatic drug protocols and early intervention have improved the prognosis, not all patients do well, even in the postbiologic era.

Ankle involvement is almost always preceded by subtalar joint involvement and may be a consequence of altered hindfoot alignment associated with long-standing subtalar disease.¹⁸ Subtalar joint disease is accompanied by pain on walking on uneven ground and swelling posterior to the medial malleolus or in the sinus tarsi.¹⁹ Over time, synovitis and mechanical loads lead the hindfoot to function in a progressively more valgus position.²⁰ The deformities are largely reducible initially, and in this phase functional foot orthoses have been shown to restore normal function and to slow the progression of fixed deformity.²¹ If the deformities are uncorrected, bony adaptation occurs and the changes become irreversible. In the presence of significant deformity, use of adaptive footwear might be necessary.

In the severely valgus rheumatoid foot, synovitis and compression of tissues of the medial hindfoot can lead to tarsal tunnel syndrome as described earlier. Other soft tissue manifestations include retrocalcaneal bursitis, nodules over areas of mechanical irritation, and tenosynovitis of long flexor and extensor tendon sheaths leading sometimes to the development of

Fig. 78.4 Marked thickening of fascia (arrows) at calcaneus (C) with more normal structure distally (arrowheads).

Fig. 78.5 Planovalgus deformity.

Fig. 78.6 Plain radiograph showing the characteristic hallux valgus-type changes in a foot with rheumatoid arthritis.

intrasubstance tears and degeneration. In tendons subject to high mechanical demands, such as the tendon of the tibialis posterior, this can occasionally result in complete rupture of the tendon. Varus deformities of the hindfoot are rare, occurring in fewer than 1 in 30 people with RA.²² The joints of the midfoot are often affected, with the talonavicular joint and tarsometatarsal joints affected in 15% to 30% of cases. Diffuse joint degenerative change may be evident, but the characteristic erosions seen in the forefoot are rare.

In the forefoot, severe synovitis can result in a typical “daylight” sign in which neighboring toes are separated by the soft tissue mass. Persisting synovial inflammation causes stretching and weakening of the joint capsule and loss of integrity of the stabilizing structures in the forefoot.²³ The hallux valgus-type deformity of RA is severe, often resulting in subluxation of the first MTP joint. The second, third, and fourth toes develop a hammer toe deformity and exhibit lateral drift, whereas the fifth toe drifts toward the midline, coming to lie over or under the fourth. In cases in which forefoot deformity is severe the lesser digits no longer contribute to weight bearing, and when this is combined with anterior displacement and atrophy of the plantar fat pads, significantly increased pressure under the MTP joints can result.²⁴ Intermetatarsal bursae protrude onto the plantar surface or prominent adventitious bursae can develop under the metatarsal heads, and these prominences can be overlaid with hyperkeratosis (Fig. 78.7). Bursitis at this site is painful, and localized areas of skin ulceration are not uncommon. Patients often describe a sensation of “walking on pebbles.”

The evidence of benefit for most treatments relating to the foot in RA is not especially strong, although some countries have been able to formulate guiding principles. There is some evidence that use of contoured functional foot orthoses reduces foot pain and improves function in people with RA,²⁵ although a subsequent review of the use of foot orthoses in patients with RA indicated a lack of consensus on the precise types of orthoses likely to perform best.²⁶

Fig. 78.7 Prominent intermetatarsal bursae with overlying hyperkeratosis. (From Frowen P, O'Donnell M, Burrow D, Lorimer G, editors. *Neale's disorders of the foot*, 8th ed. Churchill Livingstone, Edinburgh; 2010. With permission.)

Provision of therapeutic footwear has been shown to provide symptom relief and improvement in function in patients with RA. Traditionally, therapeutic footwear was made to measure, but the high costs and poor patient satisfaction have led to a change in approach.²⁷ Off-the-shelf shoes have been shown to provide significant improvements in pain, quality of life, and gait parameters.²⁷ There is evidence of similar levels of satisfaction with custom-made and off-the-shelf shoes in people with RA. In one Dutch study about one third of RA patients had been provided with therapeutic footwear, some 80% of which were in daily use.²⁸

Soft flexible uppers made of soft leathers or stretchable textile can reduce the pressure on deformed toes, and the demand for painful motion in the forefoot joints during walking can be addressed by the provision of shoes with a rocker sole. If patients experience difficulties with shoe fastenings, standard laces can be changed for elastic laces in existing shoes or other fastenings such as Velcro or elastic can be considered.

Soft tissue presentations such as prominent bursae or nodules can respond well to the use of pressure-relieving insoles and padding. Plantar callosities that build up over metatarsal heads can benefit from a similar approach. Scalpel débridement of hyperkeratosis appears ineffective if used in isolation, however, and should be combined with other interventions to prevent recurrence of symptoms.²⁹

Most surgical procedures are performed relatively late in the disease process and include tarsal tunnel decompression and ankle, subtalar, or talonavicular arthrodesis as well as a range-of-forefoot procedures.³⁰ Subtalar arthrodesis can be required following rupture of the tendon of the tibialis posterior if tendon repair is not possible and the region is mechanically unstable.¹⁹ The end-stage procedure is triple arthrodesis with corrective wedge osteotomies to restore alignment (Fig. 78.8). In the forefoot, excision arthroplasty is a part of most procedures, and the metatarsal heads, the proximal third of the phalanges, or both are usually excised. All lesser MTP joints are usually operated on simultaneously because more selective approaches tend to have poorer long-term results in people with RA.³¹ Modern variations, including techniques involving interposition of the plantar plate and preservation of the metatarsal head, are gradually supplanting the more traditional approaches.³²

JUVENILE IDIOPATHIC ARTHRITIS

In the polyarticular form of juvenile idiopathic arthritis, the foot is involved in about two thirds of cases,³³ predominantly at the hindfoot. When the ossification centers are involved, there may be an effect on the growing bones leading to deformity and brachydactyly. Pes planus or pes cavus deformities are common, as is the hallux valgus-type deformity also described previously in adult RA. In juveniles affected by enthesitis-related arthritis and psoriatic arthritis the clinical picture is similar to that seen in adult seronegative disease. The hindfoot and interphalangeal joints are affected, and there is enthesitis at the insertion of the Achilles tendon and plantar fascia. Ongoing inflammation in midfoot and hindfoot joints may lead to ankylosis. Attention should be given to the feet in juvenile idiopathic arthritis because deformity occurs quickly. Children are usually compliant with the use of in-shoe orthoses, but regular review is required.

Fig. 78.8 Triple arthrodesis of subtalar, talonavicular, and calcaneocuboid joints.

OSTEOARTHRITIS

The ankle and foot have not generally been considered an important anatomic region in osteoarthritis (OA). The ankle is remarkably resistant to OA for a weight-bearing joint,³⁴ and presentations of OA in the feet are often trivial relative to OA in the hips and knees. When the ankle joint does develop OA it is usually a consequence of major trauma such as complex ankle fracture, repeated minor trauma such as chronic ankle instability, or inflammatory arthritis. There are no good data about foot OA because of lack of consistency in definitions and resulting poor case ascertainment in studies. The use of radiologic definitions is associated with higher estimates of prevalence overall, whereas the use of clinical definitions yield variable rates. A standardized radiographic atlas and classification system for foot joint OA has been developed in recent years, which should improve the quality of data.³⁵ Subclinical OA has been reported in half of first MTP joints in older people.³⁶ Beyond the first MTP joint, foot OA arises as a consequence of mechanical damage, trauma, or systemic disease, and studies using the new radiographic atlas have highlighted a much higher prevalence of OA than previously thought¹³ in regions such as the midfoot (Fig. 78.9). Importantly, foot OA usually presents in combination with pain in other joints such as knees, back, hands, and hips, which increases the impact.⁵

The most obvious presentation of OA in the foot is in the first MTP joint, where the degenerative change presents as limitation, fixation, or deformity of the hallux joint (known as *hallux limitus*, *hallux rigidus*, or *hallux valgus*). Periarticular osteophyte causes thickening of the joint, sometimes with an overlying bursa. OA in the foot is a predictor of health care service use, with the presence of foot OA doubling the risk of reliance on health services.³⁷ Treatments for OA of the foot are of variable efficacy, however. NSAIDs and acetaminophen are cornerstones, and weight loss and low-impact exercise are of known benefit.³⁸ Local therapies are directed at abnormal biomechanics or symptoms. The use of contoured foot orthoses can stabilize foot joints and act through offloading the forefoot and heel regions, and so may help some patients. Shock-absorbing insoles or footwear can also provide symptom relief. Accommodative padding may reduce pressure over bony prominences. Footwear adaptations such as rocker-bottom shoes lessen the movement in degenerate joints and aid sagittal plane motion. Intraarticular steroid injections may relieve symptoms,³⁹ although in practice the effect rarely lasts longer than 2 to 4 weeks. When surgical intervention is required it usually provides the definitive solution, and arthrodesis, replacement, or excision arthroplasty reduces pain significantly. Surgery of the first MTP joint is undertaken widely, and the use of more sophisticated, joint-sparing procedures have improved outcomes considerably in the past two decades.

Fig. 78.9 Midfoot osteoarthritis. (From Frowen P, O'Donnell M, Burrow D, Lorimer G, editors. *Neale's disorders of the foot*, 8th ed. Churchill Livingstone, Edinburgh; 2010. With permission.)

Surgery is required less often for the subtalar joint, ankle joint, and midfoot. Ankle joint surgery includes many variants of arthroscopic and open approaches. Unless there is advanced degeneration and deformity, arthrodesis of the ankle is considered a salvage procedure because of the significant physical demands on this joint.⁴⁰ Pantalar and triple arthrodeses are similarly regarded as salvage procedures.

Ankle and foot joint replacements have performed poorly relative to hip and knee replacements. Initial optimism from early experiments with total ankle replacement arthroplasty was followed by poor medium- and long-term results, and the technique fell from favor.⁴¹ Ongoing refinements have led to some resurgence in interest in ankle replacements, and the use of third-generation mobile bearings appears to be associated with better functional outcomes and lower failure rates,⁴² although ankle replacements do not yet approach the life span of replacements of large joints. Surgical joint distraction using external Ilizarov fixation is another experimental technique undergoing trials in the hope of inducing cartilage regeneration, and there have been some encouraging early results in severe ankle arthritis.⁴⁰

PSORIATIC ARTHRITIS AND SERONEGATIVE DISEASES

Relatively little clinical research has been carried out on the involvement of the foot and ankle in the seronegative diseases. Psoriatic arthritis (PsA) is the major form of spondyloarthritis affecting the feet, and most of the clinical studies relate to PsA. The underlying pathologic process in most of the seronegative disease is enthesitis, typically at the insertion of the Achilles tendon and origin of the plantar fascia and the multiple entheses of flexor and extensor tendons in the digits. Isolated recurrent or bilateral Achilles enthesitis should suggest a diagnosis of spondyloarthritis. In early PsA, the prevalences of plantar fasciitis and Achilles insertional enthesitis have been reported as 12% and 6%, respectively,⁴³ and hindfoot enthesitis is the defining feature in reactive arthritis. Dactylitis is the classic presenting feature of PsA in the foot, with involvement of the skin and nails usual but not universal. The presence of dactylitis is associated with more severe disease, including arthritis mutilans. Plain radiography may show typical changes such as erosion of the terminal phalangeal tufts, juxtaarticular and enthesal new bone formation, periostitis, and severe osteolysis.

The extent of articular involvement ranges from monoarthritis to a destructive erosive polyarthritis.⁴⁴ Hindfoot deformity manifesting as pes planovalgus has been reported in two thirds of established cases of PsA,⁴⁵ and forefoot involvement is even more common in established disease, with more than 90% of people with long-standing PsA having hallux valgus and claw toes.

Intraarticular steroid injections may be used to treat persistent monoarthritis or oligoarthritis, and steroids can be used with good effect at the insertions of the peroneals, the extensor and flexor tendons, and the plantar

fascia. The use of steroids around the insertion of the Achilles tendon is discouraged because of the risk of rupture. There is currently no specific evidence to support the use of special footwear and orthoses in PsA, although it is reasonable to conclude that the inflammatory and mechanical factors that affect the feet in PsA generally should be addressed in much the same way as in RA.

CONNECTIVE TISSUE DISEASES

The two most relevant connective tissue diseases (CTDs) are lupus and systemic sclerosis (SSc or scleroderma), both of which are characterized by vascular features that are found in the feet of 90% or so of individuals with CTDs. Raynaud phenomenon is almost universal, and telangiectasia and purpura are common. Severe vasculopathy in the form of vasculitis and ulceration occur in some 10% to 20% of people with CTDs, in the hands and to a slightly lesser extent in the feet.⁴⁶ Among the CTDs, SSc often gives rise to the most significant foot problems and is the focus of the rest of this section.

The initial presentation in SSc is often Raynaud phenomenon accompanied by edema of the hands or feet (Fig. 78.10). Over time the skin, particularly in the extremities, thickens and tightens. Flexion contractures compromise function, and localized calcinotic lesions may develop on the digits or other areas of mechanical stress. Involvement of the foot in SSc is less common and less severe than involvement of the hands, although the foot is affected in about 75% of patients with progressive SSc.⁴⁷ Articular synovitis does occur in SSc but in large joints more than in the foot. Any inflammatory arthropathy in the feet is usually nonerosive, although tendinopathy can sometimes be seen, especially in the Achilles tendon.

Onycholysis and pitting of the nails may be observed similar to that encountered in psoriasis. Splinter hemorrhages may also be seen in the nail beds, reflecting the vascular involvement. The effects of local vasculitis are exacerbated by concomitant large-vessel disease leading to gangrene and increased risk of amputation.⁴⁸ Vasculitic ulcers associated with SSc are often very painful, and the healing process can take many months, usually occurring through necrosis and fibrosis rather than granulation and reepithelialization.

The consequences in the feet are not well described, and although SSc has been reported to lead to difficulties with shoe fitting,⁴⁹ the precise extent of the impact is not well studied. Nevertheless, it appears sensible that patients with SSc undergo regular foot checks and have access to foot health services.

CRYSTAL ARTHROPATHIES

Acute gout presents classically in the first MTP joint (Fig. 78.11), although any of the joints of the foot may be affected. The acute gouty presentation

is of a hot, swollen joint that is exquisitely tender with a history of rapid onset. When foot joints are affected, the pain is severe enough to prevent weight bearing, but acute episodes typically settle in 10 to 14 days.

Systemic symptoms such as fever may occur, and levels of inflammatory markers such as C-reactive protein may be significantly elevated. Serum urate level may be normal in an acute attack, and an elevated serum urate level either during or after an episode is not diagnostic of gout. Infective monoarthritis can be excluded by testing of fluid aspirated from the affected joint.

Chronic (tophaceous) gout (Fig. 78.12) usually occurs insidiously and can involve the large or small joints. The chronic form is likely to be associated with radiologic abnormalities such as periarticular erosions and is arguably more worrisome than the more obvious acute attacks. Gouty tophi can develop in periarticular anatomic structures and in tendons such as the Achilles tendon. Tophaceous gout is associated with progressive deformity and impairment of function. Treatment is systemic, with the manifestations in the feet being most important for recognition of chronic uncontrolled disease.

HYPERMOBILITY SYNDROME

People with joint hypermobility have greater foot impairment than matched controls, and the severity of symptoms correlates with the severity of systemic hypermobility.⁵⁰ Treatments are aimed at improving mechanical

stability, although there is minimal formal evidence regarding efficacy. Pilates-type approaches seem helpful and building muscle strength may be advantageous. Gentle stretching can also be useful because people with hypermobile joints often have pathologic tightness of surrounding muscles and tendons. Footwear advice usually helps, and some people with mechanical foot pain benefit from the use of foot orthoses, which control joint function and stabilize specific foot joints.

ACKNOWLEDGMENTS

The temporomandibular joint

■ SHARON M. GORDON ■ JENNIFER FRANGOS ■ GARY WARBURTON

- The temporomandibular joint is covered with fibrocartilage rather than hyaline cartilage.
- Temporomandibular joint pain is common and occurs more frequently in women than in men.
- Management is generally multimodal and multidisciplinary.

BACKGROUND: EPIDEMIOLOGY AND CLASSIFICATION

Temporomandibular joint disorder (TMJD) is classified as a musculoskeletal disorder and is a major cause of chronic pain in the craniofacial region, second only to headache.¹ It is estimated that more than 5.3 million U.S. adults seek treatment annually.² The annual incidence of TMJD is 2%, with women being at higher risk than men.³ Approximately 20% of patients will progress to a persistent pain state.⁴ Although the current literature lacks universal staging criteria, most sources concur on the categories listed in Box 79.1. Importantly, more than one of these categories can occur together.

FUNCTIONAL ANATOMY

The temporomandibular joint (TMJ) is a diarthrodial synovial joint with both rotational and translational movement. It is unique in that its surfaces are covered with fibrocartilage rather than hyaline cartilage, which allows greater repair capacity and less susceptibility to degeneration. The meniscus or disk is bilaminar, also composed of fibrocartilage, and devoid of blood vessels or nerves. However, the intervening tissue is very vascular and well innervated. The meniscus and retrodiscal tissue separate the joint into superior and inferior compartments. Three functional ligaments (collateral, capsular, and temporomandibular) and two accessory ligaments

(sphenomandibular and stylomandibular) provide support for the joint. The muscles of mastication move the joint, offset loading, and maintain the condyles within the fossa. Innervation is provided by the mandibular branch of the trigeminal nerve: the auriculotemporal, masseteric, and deep temporal branches. The blood supply is derived from three branches of the external carotid artery: the superficial temporal, middle meningeal, and internal maxillary arteries. The fluid produced by the synovial lining provides nutrients to the nonvascularized meniscus. It thought that hypoxic reperfusion produces free radicals and inflammatory mediators that lead to breakdown of the lubrication system.^{5,6}

DIAGNOSIS: HISTORY AND EXAMINATION

A thorough history and physical examination are key to identifying the primary source of dysfunction, thereby helping determine treatment (Box 79.2). Pain and range of motion should be evaluated with an analog score at each visit to document improving or worsening symptoms. The quality, location, timing, and exacerbating or relieving factors should also be identified. Clinical examination includes palpation of the muscles of mastication and notation of any pain or spasms (Fig. 79.1). Pain on joint palpation and on loading of the TMJ, as well as palpable and audible joint sounds, should be recorded. Signs of parafunction such as tongue scalloping, tooth wear, and buccal ridging may be noted. A diagnostic auriculotemporal nerve block with a local anesthetic such as 3% mepivacaine may be valuable in differentiating arthrogenous pain from that attributable to other sources. Appropriate imaging should be obtained, such as magnetic resonance imaging to visualize the meniscus or computed tomography to visualize the bony elements (Fig. 79.2).

MANAGEMENT

Therapies for TMJD can be divided into two major categories: nonsurgical and surgical. Goals of management include reduction or resolution of pain and inflammation, improved function and range of motion, and reduction of joint-loading force. As a chronic pain condition with a multifactorial nature, management should likewise be multimodal.

Nonsurgical management

The majority of patients can be managed nonsurgically.⁷ Physical and psychological approaches are generally used in combination and include occlusal appliances, physical therapy, behavioral modification, and pharmacologic adjuvants. As can be seen in Table 79.1, some drugs have been studied specifically for TMJD pain. Pharmacologic management should be based on the same principles that apply to other chronic conditions: demonstrated efficacy, acceptable adverse effect profile, and safety when given for prolonged periods. In addition, a broad range of other conditions can coexist with TMJD, and such conditions need to be taken into account when considering treatment because they may modify safety or effectiveness.

BOX 79.1 CLASSIFICATION OF TEMPOROMANDIBULAR JOINT DISORDER**Myofascial pain disorder and dysfunction**

Most common, primarily of muscular origin
 Characterized by myogenous pain and limited mandibular function
 May be associated with parafunctional habits, stress, anxiety, depression, or trauma
 Internal displacement of the temporomandibular joint (disk displacement)
 Reducing or nonreducing (closed lock) with joint sounds and deviation with opening
 Most common is anteromedial displacement of the disk
 Results in mechanical interference leading to moderate to severe restriction in range of motion

Systemic diseases (arthritis such as rheumatoid arthritis, psoriatic arthritis, osteoarthritis)

Affect the joint through inflammation or degenerative processes
 May result in condylar remodeling and degenerative joint disease
 May also be related to infectious processes triggering joint inflammation

Congenital and developmental diseases (including trauma and neoplasms)

Hemifacial microsomia or condylar hyperplasia
 Infection
 Ankylosis

BOX 79.2 COMMON DIFFERENTIAL DIAGNOSES

Trigeminal neuralgia, particularly atypical trigeminal neuralgia
 Atypical facial pain, such as atypical odontalgia
 Odontogenic infection, particularly in the molar region
 Sinus or ear infection
 Salivary gland dysfunction, particularly the parotid gland

Fig. 79.1 Clinical examination of the muscles of mastication, the temporomandibular joint, and range of mandibular motion.

Fig. 79.2 Magnetic resonance images depicting disk displacement.

■ **TABLE 79.1**
Hierarchical evidence for nonsurgical pharmacologic management

Drug class	Examples
Nonsteroidal antiinflammatory drugs	Piroxicam, diclofenac, ibuprofen, celecoxib, naproxen
Muscle relaxants and benzodiazepines	Clonazepam, cyclobenzaprine, orphenadrine, and meprobamate but not carisoprodol, alprazolam, or triazolam
Antidepressants/epileptics	Amitriptyline, gabapentin
Immune-modifying drugs	Infliximab with or without methotrexate, glucosamine, chondroitin sulfate
Topically applied agents	Capsaicin cream; topical and oral diclofenac equally effective

Level of evidence at the I or II level; drug class omitted if no published trials are available.

Surgical management

A small proportion of patients are considered surgical candidates. Surgical options range from arthrocentesis, arthroscopic surgery, and modified condylotomy to total joint replacement. Absolute indications for surgical intervention are pathology, trauma, and ankylosis, whereas relative indications include those refractory to nonsurgical management only when the TMJ is directly involved. Minimally invasive measures or injections of local anesthetic, steroid, hyaluronic acid or other viscosupplementation, or botulinum toxin type A (Botox) may be useful.⁸⁻¹⁰

SUMMARY

The symptoms of TMJD may be enhanced by the mechanisms of pain amplification. Recent evidence has linked TMJD to other chronic pain disorders such as fibromyalgia, irritable bowel syndrome, chronic fatigue syndrome, and others. Therefore, it is important for practitioners to have an understanding of TMJD as a coexisting or contributory condition.

Fibromyalgia and related syndromes

■ DANIEL J. CLAUW

- Fibromyalgia can be considered both a discrete illness and a construct to help explain when and why many individuals with chronic pain centralize their pain.
- When individuals with any chronic pain state centralize their pain, they are less likely to respond to treatments (e.g., injections, surgery, opioids) that work better for acute or peripheral pain.
- Nonpharmacologic therapies can be extremely helpful for patients with fibromyalgia or centralized pain and are often underused in clinical practice.

INTRODUCTION

Clinical practitioners commonly see patients with pain and other somatic symptoms that they cannot adequately explain based on the degree of damage or inflammation noted in peripheral tissues. In fact, this may be among the most common predicaments for which individuals seek medical attention. Typically an evaluation is performed looking for a cause of the pain.

If no cause is found, these individuals are often given a diagnostic label that merely connotes that the patient has chronic pain in a region of the body, without an underlying mechanistic cause (e.g., chronic low back pain, headache, temporomandibular joint disorder). In other cases, the label given alludes to an underlying pathologic abnormality that may or may not be responsible for the individual's pain (e.g., endometriosis, facet syndrome). In the worst case scenario, these patients are told that there is nothing wrong with them, advised that the disorder is "all in their head," and given a label such as "somatizer" without being offered any treatment.

Fibromyalgia (FM) is merely the current term for chronic widespread musculoskeletal pain for which no alternative cause can be identified. Gastroenterologists often see the very same patients and focus on their gastroenterologic complaints, and often use the terms *functional gastrointestinal disorder*, *irritable bowel syndrome* (IBS), *nonulcer dyspepsia*, or *esophageal dysmotility* to explain the patients' symptoms. Neurologists see these patients for their headaches and/or unexplained facial pain, urologists for pelvic pain and urinary symptoms (and use labels such as *interstitial cystitis*, *chronic prostatitis*, *vulvodynia*, and *vulvar vestibulitis*), dentists for temporomandibular joint syndrome, and so on.

Until recently these unexplained pain syndromes perplexed researchers, clinicians, and patients. However, the following is now clear:

- Individuals sometimes have only one of these idiopathic pain syndromes over the course of their lifetime. But more often, individuals with one of these entities, and their family members, are likely to have several of these conditions.¹ This is not surprising because recent studies have shown that a variety of chronic pain conditions are very familial, and specific genetic polymorphisms that increase or decrease pain processing are rapidly being identified. Many terms have been used to describe these coaggregating syndromes and symptoms, including *functional somatic syndromes*, *somatization disorders*, *allied spectrum conditions*, *chronic multisymptom illnesses*, *medically unexplained symptoms*, among others (Fig. 80.1).
- Some of these individuals have comorbid psychiatric conditions, but at any given time, most do not. A number of different types of studies make it clear that these pain syndromes are clearly different and

separable from depression and anxiety, and have strong genetic underpinnings.

- Women are more likely to have these disorders than men (approximately 1.5 times as likely) but the sex difference is more pronounced in FM than in other chronic pain conditions because of the unintended consequences of requiring the presence of a certain number of tender points in the 1990 American College of Rheumatology (ACR) criteria. Also, clinical samples (especially for tertiary care) tend to overrepresent females compared with population-based samples.
- A hallmark of these conditions (e.g., FM, IBS, headache, temporomandibular disorder) is that individuals display diffuse hyperalgesia (increased pain to normally painful stimuli) and/or allodynia (pain to normally nonpainful stimuli). This suggests that these individuals have a fundamental problem with augmented pain or sensory processing (i.e., an increased gain setting) in the central nervous system (CNS) rather than a pathologic abnormality confined to the region of the body where the person is currently experiencing pain. These findings of centralization of pain can be corroborated by the presence of these same phenomena on functional neuroimaging studies and appear to be due in part to imbalances in levels of neurotransmitters that affect pain and sensory transmission. Because of this, CNS-mediated symptoms other than pain (fatigue, memory difficulties, sleep and mood disorders) are frequent comorbidities.
- Similar types of therapies are efficacious for all of these conditions, including both pharmacologic treatments (e.g., drugs that raise levels of antinociceptive neurotransmitters such as serotonin and norepinephrine, or lower levels of pronociceptive neurotransmitters such as glutamate and substance P) and nonpharmacologic treatments (e.g., exercise, cognitive behavioral therapy). The shared neurotransmitter hypothesis regarding the pathogenesis of these conditions suggests that because these neurotransmitters that control pain sensitivity are also known (in different and overlapping brain regions) to control sleep, level of alertness, memory, and mood, then when a patient receives a drug of the correct class of such centrally acting analgesics, the patient typically experiences improvement in many different symptoms other than just pain. The problem is that few people respond well to any single class of drug.
- Conversely, individuals with these conditions typically do not respond well when given therapies that are effective for acute pain or pain caused by damage to or inflammation of tissues (e.g., nonsteroidal antiinflammatory drugs [NSAIDs], opioids, injections, surgical procedures).

Even if a practitioner has a problem with considering FM as a discrete disorder, it is very important that he or she understand the diagnostic and therapeutic importance of centralization of pain, as exemplified by a typical FM patient. When a patient with any *rheumatic disorder* develops evidence of centralization of pain, it is likely that treatments that work well for acute pain or pain primarily due to nociceptive input (NSAIDs, opioids, antiinflammatory drugs, immunosuppressives, disease-modifying antirheumatic drugs, injections, surgical procedures) will be less effective.

HISTORICAL PERSPECTIVE

Although the term *fibromyalgia* is relatively new, this condition has been described in the medical literature for centuries. Sir William Gowers coined the term *fibrositis* in 1904. During the next half century, fibrositis (as it was then called) was considered by some to be a common cause of muscular pain, by others to be a manifestation of "tension" or "psychogenic rheumatism," and by the rheumatology community in general to be a nonentity.

Fig. 80.1 Regional or localized syndromes that overlap with fibromyalgia in prevalence, mechanisms, and treatment. ENT, ear, nose, and throat.

The current concept of FM was established by Smythe and Moldofsky² in the mid-1970s. The name change reflected the increasing evidence that there was no “-itis” (inflammation) in the connective tissues of individuals with this condition, but instead “-algia” (pain). These authors characterized the most common tender points (regions of extreme tenderness in these individuals) and reported that patients with FM had disturbances in deep and restorative sleep and that selective stage 4 interruptions induced the symptoms of FM.³ Yunus and associates⁴ then reported on the major clinical manifestations of patients with FM seen in rheumatology clinics.

The next advance in FM was the development of the ACR criteria for FM, which were published in 1990.⁵ These classification criteria require that an individual have both a history of chronic widespread pain (CWP) and the presence of 11 or more of a possible 18 tender points on examination. These ACR classification criteria were intended for research use to standardize definitions of FM. In this regard, the criteria have been extremely valuable. Unfortunately, many practitioners use these criteria in routine clinical practice to diagnose FM in individual patients, and this unintended use has led to many of the current misconceptions regarding FM, which are discussed later.

The finding of diffusely increased tenderness, as well as the failure to find inflammation in the muscles or other tissues of FM patients, caused the name of this entity to be changed from *fibrositis* to *fibromyalgia*, as noted earlier. The diffuse nature of the pain and tenderness also led many groups of investigators to begin to explore CNS mechanisms to explain the underlying pathogenesis of these disorders.^{6,7} In fact, major advances in understanding individual syndromes within this spectrum occurred only after investigators concluded that this was not a condition caused by peripheral damage or inflammation and began to explore central, neural mechanisms of these diseases.

EPIDEMIOLOGY

Chronic widespread pain

Epidemiologic studies of CWP, the historical component of the ACR criteria for FM, have been extremely instructive. CWP is typically operationalized as pain above and below the waist, involving the left and right sides of the body, and also involving the axial skeleton. Population-based studies of CWP suggest that 5% to 15% of the population has this symptom at any given time.⁸ Chronic regional pain is found in 20% to 25% of the population. Both chronic widespread and chronic regional pain occur about 1.5 times more commonly in women than in men.

Fibromyalgia

As noted earlier, the 1990 ACR criteria for FM require that an individual have both a history of CWP and the presence of 11 or more of 18 possible tender points on examination. Tender points are represented by nine paired predefined regions of the body, often over musculoskeletal insertions. If an individual reports pain when a given region is palpated with 4 kg of pressure, it is considered to be a positive finding of a tender point. Between 25% and 50% of individuals who have CWP also have 11 or more tender points and thus meet the criteria for FM. The prevalence of FM is just as high in rural or nonindustrialized societies as it is in countries such as the United States.

In 2010 and 2011, alternative criteria for FM were established that did not require performing a tender point count.^{9,10} These new criteria are aligned with a more contemporary view of the “pain centralization phenotype” which acknowledges that the most discriminating features of FM and other centralized pain states are multifocal pain (i.e., involving many areas of the body rather than just a few) combined with other comorbid symptoms such as fatigue, memory difficulties, and sleep and mood disturbances.^{11,12}

Significance of tender points

At the time the 1990 ACR criteria were first published, it was thought that there might be some unique significance to the locations of tender points. In fact, the term *control points* was coined to describe areas of the body that should not be tender in FM, and individuals were assumed to have a psychological cause of their pain if they experienced tenderness in these regions. Since then, we have learned that the tenderness in FM extends throughout the entire body. Thus, relative to the pain threshold that a normal non-FM patient would experience at the same points, control regions of the body such as the thumbnail and forehead are just as tender as FM tender points. Thus, to assess tenderness in clinical practice, practitioners can apply pressure wherever they wish, and as long as they perform this examination with the same pressure in a series of patients, they can get a good sense of the overall pain threshold of any individual patient.

The tender point requirement in the 1990 ACR criteria not only misrepresents the nature of the tenderness in this condition (i.e., local rather than widespread) but also strongly influences the demographic and psychological characteristics of FM as defined by these criteria. Women are only 1.5 times more likely than men to experience CWP but are 10 times more likely than men to have 11 or more tender points. Because of this, women are approximately 10 times more likely to meet the 1990 ACR criteria for FM than men. Most of the men in the population who have CWP but are not tender enough to meet the criteria for FM likely have the same underlying problem as the women who meet the ACR criteria for FM.

Another unintended consequence of requiring both CWP and the presence of at least 11 tender points for a diagnosis of FM is that many individuals with FM have high levels of distress. Wolfe has described tender points as a “sedimentation rate for distress” because of population-based studies showing that tender points are more common in distressed individuals.¹³ Distress is usually considered as a combination of somatic symptoms and symptoms of anxiety and/or depression. Until recently, many assumed that because *tender points* were associated with distress, *tenderness* (an individual's sensitivity to mechanical pressure) was associated with distress. However, evidence suggests that this latter association is probably due to the standard tender point technique, which consists of applying steadily increasing pressure until 4 kg is reached. In this situation, individuals who are anxious or expectant have a tendency to “bail out” and report tenderness. More sophisticated measures of tenderness apply stimuli in a random, unpredictable fashion, and the results of these tests are much less influenced by psychological status; results of these tests of pain threshold are similarly abnormal in FM.¹⁴ But because tender points are associated with high levels of distress, requiring the presence of 11 or more tender points to diagnose FM in someone with CWP increases the likelihood that these individuals will be female and/or distressed, compared with individuals with CWP and fewer than 11 tender points.

In fact, population-based studies suggest that the primary symptom of FM—CWP—is only modestly associated with distress, and distress is only weakly associated with the subsequent development of CWP.¹⁵ There are far more psychologically “normal” individuals who develop CWP than distressed or depressed people that do, and most individuals with CWP do not have or subsequently develop distress or depression. Other symptoms such as poor sleep¹⁶ are better predictors of who in the population without pain will subsequently develop pain than is psychological distress.

In summary, although many clinicians uniquely associate FM with women who display high levels of distress, much of this is an artifact of the 1990 ACR criteria requiring the presence of 11 tender points, as well as the

fact that most studies of FM have used clinical samples from tertiary care centers. When all these biases are eliminated by examining CWP in population-based studies, a clearer picture of FM can be gleaned, and CWP becomes much like chronic musculoskeletal pain in any other region of the body.

ETIOLOGY

Genetic factors

Research has indicated a strong familial component to the development of FM, as well as most other chronic pain states.¹⁷ First-degree relatives of individuals with FM display an eightfold greater risk of developing FM than those in the general population.¹ These studies also show that family members of individuals with FM are much more tender than the family members of control subjects, regardless of whether they have pain or not. Family members of FM patients are also much more likely to have IBS, temporomandibular disorder, headaches, and a host of other regional pain syndromes.¹⁸ This familial and personal coaggregation of conditions that include FM was originally collectively termed *affective spectrum disorder* and more recently has been called *central sensitivity syndromes* and *chronic multisymptom illnesses*. In population-based studies, the key symptoms that often coaggregate besides pain are fatigue, memory difficulties, and mood disturbances.

Recent twin studies have been particularly helpful in establishing that these somatic syndromes strongly coaggregate with each other, are strongly genetic, and are clearly separable from anxiety and depression.^{19,20} These studies also suggest that approximately half of the risk of developing these conditions is due to genetic factors and half to environmental factors.

Recent studies have begun to identify specific genetic polymorphisms that are associated with a higher risk of developing FM. To date, the serotonin 5-HT_{2A} receptor polymorphism T/T phenotype, serotonin transporter, dopamine 4 receptor, and catechol O-methyltransferase polymorphisms have all been noted to be seen in higher frequency in FM patients in several studies, although, as often occurs, these findings are not seen in all cohorts studied.^{21,22} It is noteworthy that most of the polymorphisms identified to date involve the metabolism or transport of neurotransmitters that are known to increase or decrease pain or sensory responsiveness and/or play a critical role in activity of the human inflammatory or stress responses. It is likely that there are scores of genetic polymorphisms and haplotypes that in part determine an individual's set point for pain and sensory processing and in part establish their subsequent risk of developing chronic pain.

Environmental factors

As with most illnesses that may have a genetic underpinning, environmental factors may play a prominent role in triggering the development of FM and related conditions. Environmental stressors temporally associated with the development of either FM or chronic fatigue syndrome include physical trauma (especially involving the trunk); certain infections such as hepatitis C, Epstein-Barr virus infection, parvovirus infection, and Lyme disease; and emotional stress.^{23,24} Of note, each of these stressors leads to CWP or FM in only approximately 5% to 10% of individuals who are exposed; the overwhelming majority of individuals who experience these same infections or other stressful events regain their baseline state of health.

FM also occurs quite commonly in individuals who initially have an autoimmune or other disorder associated with ongoing peripheral nociceptive input, which can then drive the centralization of pain.¹² At least 20% of individuals with rheumatoid arthritis, systemic lupus erythematosus, and osteoarthritis meet categorical (i.e., yes or no) criteria for FM, and there is now emerging evidence that these individuals have centralized their pain and thus have some of the same underlying CNS pain amplification mechanisms operative as those with FM.²⁵ The proportion of individuals who have centralized their pain appears to be higher yet in cohorts of individuals with lifelong ongoing peripheral nociceptive input, such as individuals with Ehlers-Danlos syndrome or sickle cell disease.

PATHOGENESIS

Role of stressors

Once FM develops, the mechanisms responsible for ongoing symptom expression are likely complex and multifactorial. Because disparate stressors

can trigger the development of these conditions, the human stress response has been closely examined for a causative role. In humans, daily hassles and personally relevant stressors seem to be more capable of causing symptoms than major catastrophic events that do not personally impact the individual. Two studies performed in the United States just before and after the terrorist attacks of 9/11 illustrate this latter point. In one study performed by Raphael and colleagues,^{25a} no difference in pain complaints or other somatic symptoms was seen in residents of New York and New Jersey who had been surveyed before 9/11 and then were surveyed immediately following the terrorist attacks on the World Trade Center. In another study^{25b} performed in the Washington, DC, region (near the Pentagon—the other site of attack) during the same time period, patients with FM had no worsening of pain or other somatic symptoms following the attack, compared to just before the attack.

To complete this vicious circle, these changes in baseline function of the stress response (i.e., of the autonomic and neuroendocrine systems, see later) that may occur following a stressor earlier in life have been shown to predict which symptom-free individuals without chronic pain or other somatic symptoms are more likely to develop these somatic symptoms. This has been noted both in population-based studies and in experiments in which healthy young adults are deprived of regular sleep or exercise.^{8,26}

This theoretical link between stress, changes in stress-axis activity, and subsequent susceptibility to development of somatic symptoms or syndromes is also supported by studies showing that patients with FM and related conditions may be more likely than nonaffected individuals to have experienced physical or sexual abuse in childhood.²⁷ Twin studies have recently supported a link between posttraumatic stress disorder (PTSD) and CWP.²⁸ Just as a lack of or cessation of exercise following trauma seems to be associated with a higher likelihood of developing pain or other somatic symptoms, a recent study of Israeli war veterans with PTSD showed that those who exercised regularly were much less likely to develop CWP or FM.

Role of neuroendocrine abnormalities

Because of this link between exposure to stressors and the subsequent development of FM, the human stress systems have been extensively studied in this condition. These studies have generally shown alterations of the hypothalamic-pituitary-adrenal (HPA) axis and the sympathetic nervous system in FM and related conditions.^{29,30} Although these studies often note either hypoactivity or hyperactivity of both the HPA axis and sympathetic nervous system in individuals with FM and related conditions, the precise abnormality varies from study to study. Moreover, these studies find abnormal HPA or autonomic function in only a very small percentage of patients, and there is tremendous overlap between patients and control subjects in any of these studies.

The inconsistency of these findings should not be surprising, because nearly all of these studies were cross-sectional studies which assumed that if HPA and/or autonomic dysfunction was found in FM, it must have *caused* the pain and other symptoms. Data now suggest a much more complicated picture. As noted earlier, there are better data suggesting that especially HPA abnormalities might represent a diathesis or be *due to* the pain or early life stress, rather than causing it.³¹ The picture is a very complicated one, with good evidence for a role of “sympathetic overdrive” (especially at night) in a subset of FM patients but not in others.^{32,33} It is likely that some of these neurobiologic alterations are shared with other syndromes that are known to be associated with HPA and/or autonomic function such as depression or PTSD. In fact, this has led some who have superficially reviewed the neurobiologic data regarding FM to conclude erroneously that this condition shares many biologic underpinnings with depression.³⁴

Augmented pain and sensory processing as a hallmark of fibromyalgia and related syndromes

Once FM is established, by far the most consistently detected objective abnormalities involve pain and sensory processing systems. Because FM is defined in part by tenderness, considerable work has been performed exploring the potential reason for this phenomenon. The results of two decades of psychophysical pain testing in FM have been very instructive.³⁵

One of the earliest findings in this regard was that the tenderness in FM is not confined to tender points but instead extends throughout the entire body. Theoretically, such diffuse tenderness could be due primarily to either psychological factors (e.g., hypervigilance, in which individuals are too attentive to their surroundings) or neurobiologic factors (e.g., the plethora of factors that can lead to temporary or permanent amplification of sensory input).

Early studies typically used dolorimetry to assess pressure pain threshold and concluded that tenderness was in large part related to psychological factors, because these measures of pain threshold were correlated with levels of distress. Also, nuances such as the rate of increase of stimulus pressure, control of pressure by the operator versus by the patient, and patient distress have been shown to influence pain threshold when it is measured in this manner. To minimize the biases associated with ascending measures of pressure pain threshold (i.e., those in which the individual knows that the pressure will be predictably increased). These studies showed the following: (1) The measures of pressure pain threshold that used random administration of pressures were not influenced by levels of distress of the individual, whereas tender point count and dolorimetry examinations were. (2) FM patients were much more sensitive to pressure even when these more sophisticated paradigms were used. (3) FM patients were not any more expectant or hypervigilant than controls. (4) Pressure pain thresholds at any four points in the body are highly correlated with the average tenderness at all 18 tender points and 4 control points (the thumbnail and forehead).

Heat, cold, and electrical stimuli

Not only is heightened sensitivity to pressure noted in FM, but other types of stimuli applied to the skin are also judged as more painful or noxious by these patients. FM patients also display a decreased threshold to heat, cold, and electrical stimuli.

Responses to other sensory stimuli

Gerster and colleagues^{35a} were the first to demonstrate that FM patients also display a low noxious threshold to auditory tones, and this finding was subsequently replicated. However, both of these studies used ascending measures of auditory threshold, so these findings could theoretically be due to expectancy or hypervigilance. A more recent study by Geisser and colleagues³⁶ used an identical random staircase paradigm to test FM patients' unpleasantness threshold for the loudness of auditory tones and for pressure. This study found that FM patients displayed low unpleasantness thresholds for both types of stimuli, and the correlation between the results of auditory and pressure pain threshold testing suggested that some of this was due to shared variance and some was unique to one stimulus or the other. Results of this study (and many others) do not support the view that generalized hypervigilance is responsible for these phenomena. The notion that FM and related syndromes might represent biologic amplification of all sensory stimuli gains significant support from functional imaging studies which suggest that the insula is the most consistently hyperactive region (see later). This region has been noted to play a critical role in sensory integration, with the posterior insula serving a purer sensory role and the anterior insula being associated with the emotional processing of sensations.³⁷

Specific mechanisms that may lead to a low pain threshold in fibromyalgia

Two different specific pathogenic mechanisms in FM have been identified using experimental pain testing: (1) an absence of descending analgesic activity, and (2) increased wind-up or temporal summation.

Attenuated diffuse noxious inhibitory control in fibromyalgia

In healthy humans and laboratory animals, application of an intense painful stimulus produces generalized whole-body analgesia. This analgesic effect, originally termed *diffuse noxious inhibitory control* (DNIC) and more recently *conditioned pain modulation*, has been consistently observed to be attenuated or absent in groups of FM patients compared with healthy controls.³⁸ This phenomenon has similarly been noted in a number of other chronic pain states, especially those closely associated with FM. Attenuated DNIC is not found in all patients with FM or chronic pain but is considerably more common in these patients than in control subjects.

The DNIC response in humans is thought to be mediated partly by descending opioidergic pathways and in part by descending serotonergic-noradrenergic pathways. In FM, the accumulating data suggest that endogenous opioidergic activity is normal or even increased (see later).³⁹ Studies directly measuring autonomic function and descending analgesic activity in both FM and IBS support the contention that dysautonomia (and thus the catecholaminergic systems) may be closely tied.⁴⁰ Moreover, positron emission tomography data show that baseline μ -opioid receptor binding is decreased in multiple pain-processing regions in the brains of FM patients, which is consistent with (but not proof of) the hypothesis that there is increased release of endogenous μ -opioid ligands in FM leading to high baseline occupancy of the receptors, rather than a deficiency of endogenous opioid release, that might in part be responsible for decreased DNIC. The biochemical and imaging findings suggesting increased activity of

endogenous opioidergic systems in FM are consistent with the anecdotal experience that opioids are generally ineffective analgesics in patients with FM and related conditions. There is even emerging evidence that blocking endogenous opioid release with the use of low-dose naltrexone might be an effective treatment strategy in some FM patients.⁴¹

In contrast, studies have suggested that there is decreased endogenous serotonergic and noradrenergic activity in FM. Studies have shown that levels of the principal metabolite of norepinephrine, 3-methoxy-4-hydroxyphenethylene, are lower in the cerebrospinal fluid (CSF) of FM patients. Similarly, patients with FM have been shown to have reduced serum levels of serotonin and its precursor, tryptophan, as well as reduced levels of the principal serotonin metabolite, 5-HIAA, in their CSF. The best evidence that low levels of these neurotransmitters is involved in the pathogenesis of FM comes from clinical trials in which nearly any compound that simultaneously raises both serotonin and norepinephrine levels (serotonin-norepinephrine reuptake inhibitors [SNRIs] such as tricyclics, duloxetine, milnacipran, tramadol) has been shown to be efficacious in treating FM and related conditions. A recent study by Yarnitsky and colleagues⁴² showed that individuals with neuropathic pain who had decreased DNIC/conditioned pain modulation at baseline were most likely to respond to duloxetine, which affirms what has been suspected for some time—that drugs with SNRI effects are likely working in part by restoring DNIC. In fact, a number of therapies used to treat FM or centralization of pain, including exercise and many complementary and alternative therapies, might be working in part by restoring descending analgesic activity.

Increased wind-up in fibromyalgia

Early experimental pain-testing studies also suggested that some individuals with FM may have evidence of wind-up, indicative of central sensitization.⁴³ More recent studies suggest that this does not occur as commonly in FM as diffuse hyperalgesia or decreased DNIC, but nonetheless it may help to further characterize patients.⁴⁴ In animal models this finding is associated with increased glutamatergic and excitatory amino acid and substance P hyperactivity.

Although experimental pain testing cannot yet identify individuals with increased glutamatergic or substance P activity contributing to FM pathogenesis, there is ample evidence that increased levels of these neurotransmitters are playing some role in FM. Four independent studies have shown that patients with FM have approximately threefold higher concentrations of substance P in the CSF compared with normal controls.⁴⁵ Other chronic pain syndromes, such as osteoarthritis of the hip and chronic low back pain, are also associated with elevated substance P levels, although chronic fatigue syndrome (which is not defined on the basis of pain) is not. Interestingly, once elevated, substance P levels do not appear to change dramatically and do not rise in response to acute painful stimuli. Thus, high substance P levels appear to be a biologic marker for the presence of chronic pain, and substance P antagonists were widely tested and then abandoned as analgesics.

There is better evidence that increased glutamatergic activity plays some role in the pathogenesis (and treatment) of FM. Glutamate is a major excitatory neurotransmitter in the CNS, and CSF levels of glutamate are twice as high in FM patients than in controls.⁴⁶ Not only are CSF glutamate levels elevated, but several recent studies using proton magnetic resonance spectroscopy demonstrated that the glutamate levels in FM patients are also elevated in key pain-processing areas of the brain such as the insula and change in response to changes in both clinical and experimental pain when patients are successfully treated.⁴⁷ A new imaging study by Harris suggests that the drug pregabalin is acting in FM in part by decreasing glutamatergic activity in the insula and thus decreasing functional connectivity between the default mode network and insula.⁴⁸ In this study individuals with the highest levels of glutamate in the insula before treatment were the ones most likely to respond to pregabalin. There is also evidence that subsets of patients respond to drugs known to be N-methyl-D-aspartate (NMDA) receptor antagonists, which suggests that glutamatergic activity is increased; unfortunately, these drugs, such as ketamine or dextromethorphan, are generally not well tolerated and thus not often practical for clinical use.

Nerve growth factor is another pronociceptive neurotransmitter that has been evaluated in FM and shown to be increased. Nerve growth factor antibodies currently are in clinical trials and are being shown to be very effective analgesics, although there have been safety issues. It is unclear if these drugs would work in FM because they would not generally enter the CNS, but they could affect centralization by reducing peripheral drive to centralization mechanisms (Fig. 80.2).

Thus a number of lines of evidence suggest that FM is a state of heightened pain or sensory processing and that this might occur because of high levels of neurotransmitters that increase pain transmission and/or low levels of neurotransmitters that decrease pain transmission (see Fig 80.2).

NEUROTRANSMITTERS THAT ARE KNOWN TO PLAY EITHER FACILITATORY OR INHIBITORY ROLES IN THE CENTRAL NERVOUS SYSTEM

Fig. 80.2 Neurotransmitters known to have either a facilitatory role (indicated in red, and generally increasing pain transmission in the spinal cord) or an inhibitory role (indicated in blue, and decreasing pain transmission) in the central nervous system. The arrows indicate the direction of the abnormality that has been identified in fibromyalgia (FM) and show that the only neurotransmitter system studied in FM that has not been found to be abnormal in a direction that would cause hyperalgesia/allodynia is the opioidergic system; that may explain why this class of drugs is not very effective in FM.

Abnormalities on functional and chemical neuroimaging

Functional neural imaging enables investigators to visualize how the brain processes the sensory experience of pain. The primary modes of functional imaging that have been used in FM include functional magnetic resonance imaging (fMRI), positron emission tomography (PET), and proton magnetic resonance spectroscopy (H-MRS).

fMRI is a noninvasive brain imaging technique that relies on changes in the relative concentration of oxygenated to deoxygenated hemoglobin within the brain. In response to neural activity, oxygenated blood flow is increased within the local brain area. Unlike SPECT and PET, which can measure baseline levels of blood flow, the fMRI BOLD signal originates from a difference between experimental conditions and does not assess baseline blood flow. Typically in FM and other pain states, individuals are administered an experimental pain stimulus, and the neuronal activation associated with this stimulus during the “on” condition is subtracted from the neuronal activation pattern seen during the “off” condition (often light touch).

The first study to use fMRI in FM patients was performed by Gracely and coworkers.⁴⁹ In this and other subsequent confirmatory studies, FM patients were shown to have greater amounts of neuronal activation in pain-processing regions of the brain than control subjects when they were given the same amount of pressure stimuli (Fig. 80.3). These findings were entirely consistent with the left shift in stimulus-response function noted with experimental pain testing and has been established in normal healthy individuals who span the entire continuum of pain thresholds. These and subsequent studies, which have generally reproduced these findings, suggest that FM patients have an increased gain or “volume setting” in brain pain-processing systems.

fMRI has also proved useful in determining how comorbid psychological factors influence pain processing in FM. For example, a study by Giesecke and colleagues⁵⁰ explored the relationship between depression and enhanced evoked pain sensations in 30 patients with FM. The authors found that the anterior insula and amygdala activations were correlated with depressive

Fig. 80.3 In top left graph, individuals with fibromyalgia (red) given a low-pressure stimulus have levels of pain and neuronal activation in areas of the brain known to be involved in pain processing (tips of arrows) that are similar to those of control subjects (green) given a stimulus with nearly twice as much pressure. Control subjects (blue) given the same low-pressure stimulus that causes pain in fibromyalgia patients rated their pain as 2 out of 20 instead of 12 out of 20 and have no neuronal activation with this amount of pressure. IPL, inferior parietal lobule; SI, primary somatosensory cortex; SII, secondary somatosensory cortex; STG, superior temporal gyrus.

symptoms, consistent with these medial and prefrontal brain regions' being involved in affective or motivational aspects of pain processing (and being more closely related to unpleasantness than to the sensory intensity of pain). However, the degree of neuronal activation in more lateral structures generally thought to be involved in the sensory processing of pain (i.e., where the pain is localized and how intense it is) were not associated with levels of depressive symptoms or the presence or absence of major depression. These data are consistent with a plethora of evidence in the pain field indicating that there are different regions of the brain responsible for pain processing devoted to sensory intensity and to affective aspects of pain sensation, and suggest that the former and latter are largely independent of each other.

A more recent advance is the use of fMRI to look at the extent to which brain regions are connected to each other (i.e., simultaneously activated or deactivated). This analysis can be applied to fMRI data acquired either when individuals are resting (resting state analysis) or when they are performing a task. The advantage of resting state analysis is that it does not require giving the participant a stimulus, and thus it potentially provides a window into measurement of brain changes associated with chronic, ongoing spontaneous pain. Another advantage is that there are many known neural networks that subserve different functions in the human brain, so the extent to which these networks are either intact or somehow disrupted by chronic pain can be examined. Napadow and Harris⁵¹ have used this technique to demonstrate that individuals with FM show increased connectivity between the default mode network (a network active when the brain is resting and not performing any specific task) and the insula—a known pronociceptive region of the brain. Furthermore, in these studies the degree of increased connectivity was related to the intensity of ongoing, spontaneous pain. A different group has shown that during a painful stimulus, connectivity is *decreased* between key antinociceptive regions (e.g., the brainstem—the origin of descending analgesic pathways) and a region they had previously identified to be a potential source of dysfunctional pain inhibition in FM.⁵² Thus these measures of connectivity hold considerable promise as potential biomarkers for pain intensity or mechanism, especially if they can be accurately and reliably measured using techniques such as electroencephalography that are more practical for use at the point of care.

PET has been used in several studies in FM. Wood and colleagues⁵³ used PET to show that attenuated dopaminergic activity may be playing a role in pain transmission in FM, and Harris and colleagues⁵⁴ showed evidence of decreased μ -opioid receptor availability (possibly due to increased release of endogenous μ -opioids) in FM.

In addition to the aforementioned use of *H-MRS* to show elevated glutamate levels, this technique has also been used by Harris and colleagues⁵⁵ to show that the levels of γ -aminobutyric acid (GABA), an inhibitory neurotransmitter, are decreased in the insula in individuals with FM.

Other serologic and biochemical abnormalities

Although these conditions all were originally thought to be autoimmune or inflammatory diseases and then later felt not to be, recent findings are leading to a reconsideration of whether subtle inflammatory changes may be responsible for some of the symptoms seen. Immunologic cascades have a role in the maintenance of central sensitivity and chronic pain, which is enhanced through release of proinflammatory cytokines by CNS glial cells; thus the traditional concept of inflammatory versus noninflammatory pain may gradually become less dichotomous. As may be expected in any complex biologic system, a delicate mechanism of checks and balances is at work in the spinal transmission of pain. Multiple inhibitory transmitters act at the spinal level to reduce the volume of pain transmission. Serotonin, norepinephrine, enkephalins, dopamine, and GABA are among the better-known players in this balance.

The amino acid tryptophan and the cytokines interleukin-8 (IL-8) and IL-6 have been shown to be different in FM patients compared with control subjects in several studies, but none has been evaluated in longitudinal studies.⁵⁶ Increased IL-8 level has been perhaps the most consistently demonstrated serum/plasma abnormality. Moreover, IL-8 level has been shown to correlate with symptoms and not to be associated with depressed FM. IL-8 levels are closely tied to autonomic function, and the findings of these increased levels could be due to the dysautonomia seen in FM and related conditions. Serum IL-6 level has also been shown to be elevated in FM in several studies. Low levels of tryptophan, a precursor for serotonin, have been found in two of three studies by three different groups.

Structural or peripheral abnormalities in fibromyalgia

Although a few studies have found mild abnormalities in the *skeletal muscles* of FM patients, these findings have been inconsistent and may be due to

deconditioning rather than the illness itself. Studies suggest that the tenderness in FM is not at all confined just to the muscle, so in aggregate most investigators have concluded that primary muscle disease is not a likely cause of the pain associated with FM.

Newer studies, however, are suggesting that the small fibers of peripheral nerves may be abnormal (e.g., decreased number, increased tortuosity) in some individuals with FM. Caro and colleagues⁵⁷ have published a series of studies suggesting that a subset of FM patients may have a mildly inflammatory small fiber neuropathy. Other groups have also identified evidence of a small fiber neuropathy in the skin in subsets of FM patients, but the meaning of this finding is not clear, because this same finding has been noted in many other chronic pain states.⁵⁸

Somewhat more concerning are the plethora of studies suggesting that there may be structural abnormalities of the brain in individuals with FM, which are aligned with other studies in the pain field suggesting that chronic pain may be a neurodegenerative disorder. There are now several groups that have used either voxel-based morphometry or diffuse tensor imaging to identify abnormalities in brain structure in individuals with FM, although the largest such study suggested that some of these abnormalities may be due to frequently comorbid psychiatric conditions that are known to demonstrate the same changes.⁵⁹ Regardless, these subtle changes in size and shape of cortical and subcortical areas in chronic pain states are allowing us to learn more about neuroplasticity in chronic pain, and the latter term is probably much more accurate than *neurodegeneration*, because these areas are known to increase in size following therapy.

Thus, if there are structural abnormalities or damage to tissues in FM, the most evidence for this is in neural tissues, rather than in the regions of the body where individuals with this condition experience pain. Furthermore, studies suggest that maintenance of central augmentation to some extent requires persistent noxious peripheral input, even in syndromes such as IBS and FM, which are characterized by the absence of well-defined, localized, pain-causing lesions. In fact, a recent study of FM patients with comorbid myofascial pain or regional joint pain showed that peripheral trigger point injections and hydroelectrophoresis aimed at reducing these peripheral pain generators ameliorated FM pain and increased pain thresholds at sites distant from the therapeutic interventions, which provides further evidence that painful peripheral stimuli contribute to the perpetuation of central augmentation processes.⁶⁰

Sleep and fibromyalgia

Because early studies by Moldofsky showed that sleep deprivation can lead to FM-like symptoms (these studies have subsequently been replicated) and more recent epidemiologic studies show that poor sleep is a very strong predictor of subsequent pain, there has been extensive work in FM to better understand the role of poor sleep in the pathogenesis of FM. However, the electroencephalographic abnormalities that were noted and initially thought to be a marker for FM, so-called alpha intrusions, have subsequently been found to be present in normal individuals and individuals with other conditions. More recent studies have used polysomnography to identify findings that occur more commonly in FM, including fewer sleep spindles, an increase in cyclic alternating pattern rate, upper airway resistance syndrome, and/or poor sleep efficiency, but other studies have found very little differences in sleep characteristics in FM patients and control subjects.^{61,62} At present, it is known that poor sleep can contribute to FM symptoms and that making sleep better is an important therapeutic target, but there is no evidence that there is any specific sleep abnormality causing FM.

Behavioral and psychological factors

In addition to neurobiologic mechanisms, behavioral and psychological factors also play a role in symptom expression in many patients with FM and other chronic pain. The rate of psychiatric comorbidity in patients with FM may be as high as 30% to 60% in tertiary care settings, and the lifetime rate of psychiatric disorders may be even higher.⁶³ Depression and anxiety disorders are the most commonly seen. However, these rates may be artificially elevated by virtue of the fact that most of these studies have been performed in tertiary care centers. Individuals who meet ACR criteria for FM who are identified in the general population do not have this high a rate of identifiable psychiatric conditions.

As already noted, population-based studies have demonstrated that the relationship between pain and distress is complex and that distress is both a cause and a consequence of pain. In this latter instance, a typical pattern is that, as a result of pain and other symptoms of FM, individuals begin to function less well in their various roles. They may have difficulties

Fig. 80.4 Suggested algorithm for the diagnosis and treatment of fibromyalgia. ANA, antinuclear antibody; CBC, complete blood count; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; RF, rheumatoid factor; SSRIs, selective serotonin reuptake inhibitors; TCAs, tricyclic antidepressants; TSH, thyroid-stimulating hormone.

with spouses, children, and work inside or outside the home, which exacerbate symptoms and lead to maladaptive illness behaviors. These include isolation, cessation of pleasurable activities, reductions in activity and exercise, and so on. In the worst cases, patients become involved with disability and compensation systems that almost ensure that they will not improve.

The complex interaction of biologic, behavioral, psychological, and behavioral mechanisms is not, however, unique to FM. Nonbiologic factors play a prominent role in symptom expression in all rheumatic diseases. In fact, in conditions like rheumatoid arthritis and osteoarthritis, nonbiologic factors such as level of formal education, coping strategies, and socioeconomic variables account for more of the variance in pain report and disability than biologic factors such as joint space width or sedimentation rate.⁶⁴

Because of the biopsychosocial nature of FM, several groups have attempted to identify subgroups of individuals with this condition who may have different presentations or respond differentially to treatment. One of the important emerging notions in this field is that in addition to patients with what are often considered the negative contributions of psychological factors, there are also subgroups of patients who are very resilient. Therapeutic attempts to instill positive psychological and cognitive characteristics may actually buffer neurobiologic factors leading to pain and other symptoms in FM. Increasingly, studies in FM and the broader pain field are also suggesting that a subset of chronic pain patients who might require particularly increased psychological attention are those with significant early life trauma. These individuals may be more refractory to other types of treatments and may need additional therapy aimed at identifying and working through these issues, even using nonintensive techniques such as journaling or emotional disclosure.⁶⁵

EVALUATION OF INDIVIDUALS WITH CHRONIC WIDESPREAD PAIN

The evaluation of an individual with chronic pain is a complex process (Fig. 80.4). Unlike with most other medical problems, simply arriving at a diagnosis is typically insufficient to guide treatment. This is because within any given pain diagnosis, there is tremendous heterogeneity with respect to the underlying causes and contributors to symptoms, and the most effective treatments. In particular, individuals with chronic pain can have greater or lesser peripheral nociceptive contributions (e.g., tissue damage, inflammation) and central nonnociceptive contributions (e.g., pain amplification, psychological factors) to their pain (Box 80.1). Therefore the differential diagnosis of chronic pain involves identifying which of these factors are present in which individuals, so that the appropriate pharmacologic, procedural, and psychological therapies can be administered.

Careful musculoskeletal history taking and examination remain the most important diagnostic tool for musculoskeletal pain. In other fields of medicine, advances in diagnostic testing have largely rendered a physical examination obsolete. However, in musculoskeletal medicine, technology confuses as much as it helps. For example, a high proportion of the healthy, asymptomatic population tests positive for antinuclear antibody or rheumatoid factor, or has abnormal findings on imaging studies. Worse yet, these diagnostic tests cannot tell the practitioner how severe the pain is, because there is typically a significant discordance between the results of laboratory or imaging studies and the severity of pain and other symptoms that the individual is experiencing.

Therefore the musculoskeletal history taking and examination must allow the clinician to arrive at the diagnosis (or, at worst, a very narrow

BOX 80.1 MECHANISTIC CHARACTERIZATION OF PAIN

Peripheral (nociceptive)	Neuropathic	Centralized
Primarily due to inflammation or mechanical damage in periphery	Due to damage or entrapment of peripheral nerves	Primarily due to central disturbance in pain processing
Responds to nonsteroidal antiinflammatory drugs, opioids	Responds to both peripheral and central pharmacologic therapy	Tricyclic, neuroactive compounds most effective
Responds to procedures	Examples: ■ Diabetic painful peripheral neuropathy	Behavioral factors more prominent
Behavioral factors minor	■ Postherpetic neuralgia	Examples
Examples: ■ Osteoarthritis		■ Fibromyalgia
■ Rheumatoid arthritis		■ Irritable bowel syndrome
■ Cancer pain		■ Tension headache
		■ Idiopathic low back pain

differential diagnosis), and then, if necessary, further diagnostic testing should be used to confirm these findings.

DIAGNOSIS

The ACR criteria for FM were never intended to be used as strict diagnostic criteria for application in clinical practice. Many individuals who clearly have FM do not have pain throughout their entire body or do not have 11 tender points. Moreover, pain and tenderness occur across a continuum in the population, and it is impossible to know where to draw the line between an individual with symptoms and someone with an illness.

For this and many other reasons, the alternative 2010 FM criteria may represent a preferred manner of diagnosing or thinking about FM.^{9,10} The survey version of these criteria consists entirely of patient self-report and can be administered on a single piece of paper. There is a body map with 19 areas and well as a symptom survey that asks about the presence and severity of fatigue, sleep disturbances, memory difficulties, and mood problems. When used as a dichotomous measure with a variety of cut points, this tool will identify roughly the same group of individuals as the old criteria (except many more males will be included).^{9,10} However, when FM is considered more as a physiologic construct to determine where on the continuum of pain sensitivity an individual lies, then this tool can be used as a continuous measure (i.e., to determine the degree of “fibromyalgia-ness” or the degree to which pain is centralized) that can be helpful in the diagnosis and treatment of virtually any patient with a rheumatic disorder who is experiencing pain.

History Pain

In clinical practice, one should suspect FM in individuals with multifocal pain that cannot be fully explained on the basis of damage or inflammation in those regions of the body. In most cases, musculoskeletal pain is the most prominent feature, but because pain pathways throughout the body are amplified, pain can be perceived anywhere. Thus chronic headaches, sore throats, chest pain, abdominal pain, and pelvic pain are very common in individuals with FM, and patients with chronic regional pain in any of these locations are more likely to have FM. It is especially helpful to take a lifetime history of chronic pain. Individuals with conditions such as FM nearly always begin having chronic pain in various regions of their body early in life (e.g., dysmenorrhea, functional abdominal pain, growing pains), and this continues throughout their life. What often looks to one subspecialist like a new episode of pain in the region of the body that is that practitioner's purview is in fact one in a series of chronic pain conditions that have occurred over the lifetime of the individual.⁶⁶

Because pain is a defining feature of FM, it is helpful to focus on the features of the pain that can help distinguish it from other disorders. The pain of FM is typically diffuse or multifocal, often waxes and wanes, and is frequently migratory. These characteristics of central pain are quite different from those of peripheral pain, in which both the location and severity of pain are typically more constant. Patients may complain of discomfort when they are touched or when wearing tight clothing and may experience dysesthesias or paresthesias that accompany the pain. For this latter reason

self-report measures such as the PainDETECT questionnaire that assess both the character and spatial extent of pain have been shown to be helpful in differentiating pain of neural origin (such as that of FM) from pain due to peripheral nociceptive input.

Nonpain symptoms

Aside from the pain, a number of seemingly nonrelated symptoms may develop and persist. These include fatigue, sleep difficulties, weakness, problems with attention or memory, unexplainable weight fluctuations, and heat and cold intolerance. “Allergies” are reported much more commonly in FM patients, although these excess symptoms are better considered sensory hypersensitivities than true immunoglobulin E-mediated immunologic reactions. These patients are also more prone to nonallergic rhinitis, sinus and nasal congestion, and lower respiratory tract symptoms, all of which again may be attributable primarily to neural mechanisms. Distortions in hearing, vision, and vestibular symptoms are often reported, as are sicca symptoms (sometimes so prominent that these individuals will overlap with those with Sjögren syndrome).

“Functional disorders” involving visceral organs have long been noted to be more common in FM. These include noncardiac chest pain, heartburn, and palpitations, and the frequent comorbidity of IBS. Thus there are reports of increased echocardiographic signs of mitral valve prolapse and esophageal dysmotility, and reduced static inspiratory and expiratory pressure on pulmonary function tests. The latter might be explained by pain in respiratory muscles. Syncope and hypotension are symptoms that may occur in FM, and in some cases are accompanied by neurally mediated hypotension or postural orthostatic tachycardia. Pelvic complaints are common, including not only pain but also urinary frequency and urgency. In females the frequent comorbid diagnoses are dysmenorrhea, interstitial cystitis or painful bladder syndrome, endometriosis, and vulvar vestibulitis/vulvodynia, whereas in males similar symptoms are sometimes diagnosed as chronic or nonbacterial prostatitis.

Physical examination and laboratory investigations

Critical information can be gleaned from the history and physical examination findings that can further help identify individuals with FM or centralized pain. It might seem a leap to move from experimental pain testing, brain imaging, and genetic studies of centralized pain states to a better understanding of the diagnosis and treatment of any chronic pain, but in reality this is not such a stretch. Much of the same information obtainable via these sophisticated research methods can also be gained (albeit less precisely) by taking a history and performing a physical examination.

For example, individuals with centralized pain states very often demonstrate an altered noxious threshold (the point at which a sensory experience such as pressure, heat, or sounds become bothersome) for virtually every type of sensory stimulus.⁶⁷ This can be easily understood by patients and clinicians alike when the phenomenon is likened to an increased volume control in the brain for any sensory stimulus. Because of this, individuals with FM or other centralized pain states often note that they find noises, odors, and bright lights very bothersome, and this sensory sensitivity likely even explains many of the visceral symptoms these individuals experience (e.g., indigestion, heartburn, abdominal pain, urinary urgency and frequency). These are often noted on a review of systems. Sometimes merely highlighting this physiologic understanding of sensory augmentation can be extremely helpful to patients because they are less concerned that something is wrong when they develop new symptoms that follow this same pattern—symptoms that before would often trigger a frustrating search for the cause of the pain.

Also, although pain threshold testing is not available in routine clinical practice, there are many ways that a clinician can assess for overall pain sensitivity. For examples, individuals with FM are more sensitive to the inflation of a blood pressure cuff.⁶⁸ Another way to assess overall pain threshold while also obtaining other valuable diagnostic information is to assess pain thresholds in the hands and arms of all patients with chronic pain. A rapid examination performed by applying firm pressure over several interphalangeal joints of each hand, also over the adjacent phalanges, and then caudally to include firm palpation of the muscles of the forearm, including the lateral epicondyle region, is one way to assess overall pain threshold as well as get additional diagnostic information about the patient. If the individual is tender in many of these areas, or in just the muscles of the forearm, he or she is likely diffusely tender (i.e., has a low central pain threshold). However, if the individual is tender only over the interphalangeal joints and not the other regions, and especially if there is any swelling over these joints, the practitioner should be more concerned about a systemic autoimmune disorder (e.g., rheumatoid arthritis, lupus).

Alternatively, sometimes individuals are tender only over the phalanges, and in these instances one might suspect a metabolic bone disease or condition causing periostitis (e.g., hypothyroidism, hyperparathyroidism).

Laboratory testing is generally not useful except for the purpose of differential diagnosis. One factor that can help guide the intensity of the diagnostic workup is the length of time the patient has had symptoms. If the patient's symptoms have persisted for several years, minimal testing is required, whereas a more aggressive strategy should be employed for acute or subacute onset of symptoms. Simple testing should be limited to complete blood count and routine serum chemistry panels, along with thyroid-stimulating hormone level and erythrocyte sedimentation rate and/or C-reactive protein level.

Serologic studies such as antinuclear antibody and rheumatoid factor assays should generally be avoided unless there are historical features not seen in FM or abnormalities on physical examination.

Aside from the many comorbid conditions already discussed, FM may present similarly to a number of disorders or concurrently with other disorders that may confuse the diagnosis. Hypothyroidism and polymyalgia rheumatica can be differentiated from FM by results of thyroid-stimulating hormone level and erythrocyte sedimentation rate. Sleep apnea, Chiari malformation, celiac sprue, and hepatitis C also simulate FM and tend to present more often in men than women.

TREATMENT

Progress in the understanding of FM has led to more therapeutic options for patients with this condition. Investigators are examining the utility of newer medications as well as nonpharmacologic interventions in controlled trials. It is important to use symptom-based pharmacologic therapy together with nonpharmacologic therapies because medications typically target symptoms, whereas nonpharmacologic treatments target dysfunction and functional decline (Fig. 80.5).⁶⁹

Diagnostic labeling

Once a physician rules out other potential disorders, an important and at times controversial step in the management of FM is asserting the diagnosis. Despite some assumptions that being labeled with FM may adversely affect patients, many studies have now suggested that this is not typically the case, in part because individuals stop looking for the cause of their pain and therefore see fewer subspecialists and undergo less diagnostic testing once they are diagnosed with FM.⁷⁰ Nonetheless, in certain select individuals, such as adolescents or young adults or overtly anxious persons, the preferred route may still be to avoid a label. Regardless, confirmation of the diagnosis ideally should be coupled with patient education, an intervention shown to be effective in randomized controlled trials.

Fig. 80.5 An example of dually focused treatment.

Pharmacologic therapy

The majority of clinical trials in FM have examined the use of antidepressants of one class or another. Trials studying the oldest class of agents, tricyclic antidepressants (TCAs), are most abundant, although several recent studies have focused on selective serotonin reuptake inhibitors and atypical antidepressants, a class that includes dual reuptake inhibitors and monoamine oxidase inhibitors.

Tricyclic antidepressants

The most frequently studied pharmacologic therapy for FM is low doses of tricyclic compounds. Most TCAs increase the concentration of serotonin and/or norepinephrine (noradrenaline) by directly blocking their respective reuptake. The effectiveness of TCAs, particularly amitriptyline and cyclobenzaprine, in treating the symptoms of pain, poor sleep, and fatigue associated with FM is supported by several randomized controlled trials.⁷¹ Tolerability is a problem but can be improved by beginning at very low nighttime doses (e.g., 10 mg of amitriptyline or 5–10 mg of cyclobenzaprine), giving the dose a few hours before bedtime, and very slowly escalating the dose. Very-low-dose cyclobenzaprine has recently been shown to be quite effective in a subset of individuals with FM who have a specific sleep architecture, and seemingly causes fewer adverse effects than seen in some of the earlier studies using higher dosages.⁷²

Serotonin and norepinephrine reuptake inhibitors

Because of their better adverse effect profile, a newer class of antidepressants—the selective serotonin reuptake inhibitors (SSRIs)—is frequently used in FM. The SSRIs fluoxetine, citalopram, and paroxetine have all been evaluated in randomized placebo-controlled trials.⁷³ In general, the results of studies of SSRIs in FM have paralleled the experience in other pain conditions. The newer highly selective serotonin reuptake inhibitors such as citalopram seem to be less efficacious than the older SSRIs, which have some noradrenergic activity at higher dosages.⁷⁴

Because TCAs and high dosages of certain SSRIs such as fluoxetine and sertraline that have the most balanced reuptake inhibition are the most effective analgesics, many have concluded that dual-receptor inhibitors such as serotonin-norepinephrine and norepinephrine-serotonin reuptake inhibitors (SNRIs and NSRIs) may be of more benefit than pure serotonergic drugs.⁷⁴ These drugs are pharmacologically similar to some TCAs in their ability to inhibit the reuptake of both serotonin and norepinephrine but are differ from TCAs in being generally devoid of significant activity in other receptor systems. This selectivity results in diminished adverse effects and enhanced tolerability. Some data are available for venlafaxine, the first available SNRI, to support its use in the management of neuropathic pain, but studies in FM have yielded conflicting results.

Two newer SNRIs, duloxetine and milnacipran, have undergone recent multicenter trials and were shown to be effective in terms of a number of outcome variables; both are now approved in the United States for the treatment of FM.^{75,76} These drugs seem roughly comparable in overall efficacy profile, with studies generally noting modest improvement (although not reaching statistical significance in all studies) in domains such as pain, overall improvement, physical functioning, level of fatigue, and degree of reported physical impairment. For both compounds these effects seemed to be independent of the drug's effect on mood, which suggests that the analgesic and other positive effects of this class of drugs in FM is not simply due to their antidepressant effects. Both of these drugs are better tolerated if taken with food; patients should be warned about likely initial nausea, counseled that this typically resolves in a week or so, and told to discontinue the drug if the nausea persists. The maximum approved dosage of duloxetine is 60 mg/day, but it was studied in trials at doses of up to 120 mg and shown to be safe. Similarly, the initial dose of milnacipran is 100 mg/day, but some patients benefit from increasing the dose as high as 200 mg. Hypertension is more likely to be a problem with milnacipran because it appears to be more noradrenergic; for the same reason it might be slightly more likely to help with symptoms such as fatigue.

Esreboxetine, a selective norepinephrine reuptake inhibitor, was also tested and shown to be efficacious in treatment of FM.⁷⁷ This finding adds to emerging evidence suggesting that norepinephrine reuptake activity may be much more important than serotonergic reuptake for analgesic effects.

Other drugs acting on the central nervous system

Some antiepileptic drugs have been shown to be effective in the treatment of various chronic pain conditions, including postherpetic neuralgia and painful diabetic neuropathy. Pregabalin and gabapentin have the same mechanism of action and bind to the $\alpha_2\delta$ subunit of calcium channels, and both are approved for the treatment of neuropathic pain as well as several

other indications. Several studies have shown the efficacy of pregabalin against pain, sleep disturbances, and fatigue compared with placebo in FM; as a result pregabalin was the first drug approved in the United States for use in this condition.⁷⁸ Gabapentin has been shown to have very similar efficacy and adverse effect profile in FM. The tolerability of these drugs can be dramatically enhanced by beginning at a low dose, and giving either two thirds of the dose or the entire dose at bedtime. The maximal approved dosage of pregabalin is 450 mg/day, but in trials it was studied at dosages as high as 600 mg/day and was shown to be safe and efficacious. The dosage of gabapentin needed for analgesic effect is often 1800 to 2400 mg/day. Another antiepileptic compound, clonazepam, has demonstrated efficacy in treating temporomandibular disorder and associated jaw pain; it is also useful in the treatment of restless leg syndrome and may be of value in FM.

Sedative-hypnotic compounds are widely used by FM patients. A handful of studies has been published on the use of certain nonbenzodiazepine hypnotics such as zopiclone and zolpidem in FM. These reports have suggested that these agents can improve the sleep and perhaps the fatigue level of FM patients, although they had no significant effects on pain.

On the other hand, γ -hydroxybutyrate (also known as *sodium oxybate*), a precursor of GABA with powerful sedative properties, was recently shown to be quite efficacious in improving fatigue, pain, and sleep architecture in patients with FM.⁷⁹ Note, however, that this agent is a scheduled substance due to its abuse potential and was not approved by the U.S. Food and Drug Administration (FDA) because of safety concerns. Nonetheless, these studies along with the H-MRS findings showing low GABA suggest that other less toxic GABA agonists may have an important role in treating FM.

Cannabinoids are another class of drugs in which there is renewed interest for treatment of chronic pain states. There have been two randomized controlled trials examining the use of synthetic cannabinoids in FM (both using nabilone), and both studies concluded that the drug was efficacious (in one study for improvement of both pain and sleep, in the other study at a lower dose just for sleep improvement).⁸⁰ This is not surprising because there is increased recognition that this class of drugs may have utility in treating pain of neural origin.

Pramipexole is a dopamine agonist indicated for Parkinson disease that has shown utility in the treatment of periodic leg movement disorder. One study suggested that this compound may improve both pain and sleep in FM patients, but these results have not been replicated with this or other dopamine agonists. Because of this, this class of drug may be best reserved for individuals with other indications, such as concurrent restless legs syndrome.

Tizanidine is a centrally acting α_2 -adrenergic agonist approved by the FDA for the treatment of muscle spasticity associated with multiple sclerosis and stroke. Literature suggests that this agent is a useful adjunct in treating several chronic pain conditions, including chronic daily headaches and low back pain. A randomized controlled trial examining the use of this drug in FM showed significant improvements in several parameters including sleep and pain, and treatment with tizanidine resulted in a reduction in substance P levels in the CSF of patients with FM.

Analgesics

There have been no adequate randomized, controlled clinical trials examining the use of opiates in FM, and most in the field (including the author) have not found this class of compounds to be effective in anecdotal experience. Tramadol is a compound that has some opioid activity (weak μ agonist activity) combined with serotonin-norepinephrine reuptake inhibition. This compound does appear to be somewhat efficacious in the management of FM, as both an isolated compound and in fixed-dose combination with acetaminophen.

In addition to the previously cited mechanistic studies suggesting why opioids might not be effective in FM (i.e., PET evidence of decrease opioid receptor availability, and high CSF levels of endorphins), recent functional and chemical imaging studies by the same group suggest an even more important potential problem. In these studies there is evidence that the native state of FM may be akin to that of opioid-induced hyperalgesia, in that the regions with the lowest receptor occupancy are the most hyperalgesic. Thus it is possible that in at least a subset of individuals, opioids may make the hyperalgesia worse rather than better. This notion is also supported by previously cited clinical studies suggesting that opioid antagonists may be effective in FM. If opioids are used in patients with refractory FM, it is possible that those opioids with mixed opioid antagonist effects (e.g., buprenorphine), norepinephrine reuptake inhibition (tapentadol), or NMDA receptor blockade (methadone) might be better than pure μ agonists, but this is entirely conjecture.

A large number of FM patients use NSAIDs and acetaminophen. Although numerous studies have failed to confirm their effectiveness as analgesics in FM, there is limited evidence that patients may experience enhanced analgesia when treated with combinations of NSAIDs and other agents. This phenomenon may be a result of the presence of concurrent peripheral pain conditions (due to damage or inflammation of tissues, e.g., osteoarthritis, rheumatoid arthritis) and/or worsening of central pain by these comorbid peripheral pain generators.

Neurostimulatory therapies

A variety of neurostimulatory therapies can be effective in treating musculoskeletal pain. For some time, transcutaneous electrical nerve stimulation (TENS) has been used to treat musculoskeletal pain. Conventional TENS (C-TENS) is given at a high stimulation frequency and low intensity. Pain relief is immediate, but short-lived, when it occurs. Acupuncture-like TENS (often abbreviated *AI-TENS*) is given at a lower frequency and higher intensity (which is sometimes uncomfortable), and when it works generally has a longer-lasting effect than C-TENS. These neurostimulatory therapies would be expected to be most helpful for pain of peripheral/nociceptive origin.

A new set of neurostimulatory therapies is emerging that would be expected to be more effective for centralized pain, because these therapies all aim to stimulate the CNS and, in doing so, modulate CNS pain transmission. Many such therapies have been developed and tested, with many showing some efficacy in treating several pain states. These include noninvasive techniques such as repetitive transcranial magnetic stimulation (rTMS), transcranial direct-current stimulation (tDCS), and newer ways of noninvasively stimulating brain structures. Although the studies to date using these therapies have yielded somewhat inconsistent results, a trend is emerging suggesting that these treatments might be most effective in centralized rather than purely peripheral pain states, and with stimulation parameters that enable signals to travel into deeper cortical tissues than occurs with typical delivery of rTMS and tDCS. Other more invasive techniques, such as spinal cord stimulation, deep brain stimulation, and vagal nerve stimulation, have also shown promise in patients with more refractory pain states.

Other nonpharmacologic therapies

The two best-studied nonpharmacologic therapies are cognitive-behavioral therapy and exercise. Both of these therapies have been shown to be efficacious in the treatment of FM as well as a plethora of other medical conditions.^{69,81} Both of these treatments can lead to sustained improvements (i.e., longer than 1 year) and are very effective when an individual complies with the therapeutic regimen.

Complementary and alternative therapies have been explored by patients managing their own illness as well as by health care providers. As with other diseases, there are few controlled trials to advocate their general use. Trigger point injections, chiropractic manipulation, acupuncture, and myofascial release therapy are among the more commonly used modalities and achieve varying levels of success.

Sham-controlled trials of acupuncture in FM have generally showed no difference between active and sham treatments, but recent work in the acupuncture field suggests that there might be no such thing as an inert sham acupuncture site. A comparison group receiving usual care was not included in these studies in FM, and when this has been done in studies of other chronic pain conditions the effect of acupuncture typically exceeds that of usual care. The use of tai chi in FM has also been studied in several randomized controlled trials and appears to be effective in some individuals.

PROGNOSIS

The prognosis of FM depends largely on where the individual falls on a continuum. At one end of the continuum are individuals in the population with CWP or individuals with FM who are seen in primary care, and the prognosis in these individuals is reasonably good. On the other end are individuals with FM seen in tertiary care settings, who do quite poorly. In this latter group, studies have found little change in symptoms over time, and no significant change in health satisfaction, symptoms, or functional disability.

With regard to function in FM, studies have reported varying disability rates ranging from 9% to 44%. Disability has been most strongly associated with functional and work status, pain, mood disturbances, coping ability, depression, pending litigation, and educational background.

SUMMARY

Much has been learned about chronic pain by studying FM. FM is now viewed as the prototypical central pain syndrome, occurring primarily because of spinal and supraspinal mechanisms involved in pain transmission, rather than because of peripheral inflammation or damage, or nerve damage. The same mechanisms that lead to centrally mediated pain also lead to other somatic symptoms such as fatigue and insomnia, likely because similar neurotransmitter imbalances can also cause these symptoms. Because of this, any patient with chronic pain, especially widespread multifocal pain that is accompanied by other somatic symptoms and syndromes, should be considered as possibly having comorbid FM or an element of FM (see Fig. 80.4).

Wolfe and coworkers¹³ have clearly demonstrated that FM is *both* a discrete illness (i.e., in an individual with FM) *and* the end of a continuum

of pain processing. Wolf has performed seminal work in showing that the degree of fibromyalgia-ness in an individual with any rheumatic disorder (including individuals with osteoarthritis, rheumatoid arthritis, regional pain syndromes, etc.), as measured by his Symptom Inventory, is closely correlated with the individual's level of pain and/or disability, even if the person does have a peripheral cause for the pain. The Symptom Inventory (or other measures of the current or lifetime level of somatic symptoms or somatization) is a very good measure of whether an individual has an illness on this spectrum or an element of central sensitivity, regardless of the presence or absence of a peripheral cause for the pain. A better understanding of the underlying mechanisms and most effective treatment for this spectrum of illness is critical to rheumatologists because, as Wolfe has taught us, many patients with rheumatic disorders have a little, or a lot, of fibromyalgia-ness.

Entrapment neuropathies and compartment syndromes

■ BANSARI GUJAR ■ RAYMOND H. FLORES

- An entrapment neuropathy results from increased pressure on a nerve as it passes through an enclosed space.
- Knowledge of the anatomy of each potential site of entrapment is essential for an understanding of the clinical manifestations of these syndromes.
- Conservative measures such as splinting, nonsteroidal antiinflammatory drugs, and local corticosteroid injections usually suffice when the symptoms are mild and of short duration. Surgical procedures to decompress the nerve are indicated for more severe cases.

INTRODUCTION

Entrapment neuropathy results from increased pressure on a nerve as it passes through an enclosed space. Nerves are most vulnerable as they traverse a fibroosseous canal because of disproportionate contents and capacity. Familiarity with the anatomy of each site is essential to completely understand the manifestations of each syndrome.

The signs and symptoms that accompany nerve entrapment may at times be subtle and easily confused with those of rheumatic disorders. In addition, rheumatic diseases that manifest synovitis or tenosynovitis are capable of causing compression neuropathy. Because entrapment neuropathies produce focal neurologic deficits, other conditions that can exhibit similar patterns (e.g., vasculitis, radiculopathy, reflex sympathetic dystrophy) must be included in the differential diagnosis.

Neural entrapment can occur at many sites (Table 81.1). This chapter focuses on the compressive neuropathies most often encountered in clinical practice.

THORACIC OUTLET SYNDROME

Thoracic outlet syndrome (TOS) results from compression of one or more of the neurovascular elements that pass through the superior thoracic aperture. Neurogenic entrapment accounts for the majority of the symptoms. In those relatively rare cases with clear-cut involvement of the brachial plexus, the disorder is referred to as true neurogenic TOS. Nonspecific or disputed TOS refers to patients with more poorly defined pain syndromes.¹

Anatomy

The thoracic outlet consists of several narrow channels through which the subclavian vessels and the lower trunk of the brachial plexus (eighth cervical and first thoracic fibers) pass from the thoracocervical region to the axilla (Fig. 81.1). The first area of narrowing and potential entrapment is between the scalenus anterior and medius muscles as they attach to the first rib. Next is the costoclavicular space, which is bordered by the clavicle anteriorly, the first rib posteromedially, and the superior margin of the scapula posterolaterally. Finally, the neurovascular bundle travels under the coracoid process and beneath the pectoralis minor tendon.

Etiology

Because the thoracic outlet has three well-defined areas of narrowing, traditional teaching has ascribed specific clinical syndromes to each area. Thus,

a fairly rigid classification has evolved that includes the anterior scalene, costoclavicular, and hyperabduction syndromes. However, it is more likely that anatomic abnormalities and trauma involving the shoulder girdle region have a far more pivotal role in causing this syndrome.

Cervical ribs, some incomplete with fibrous attachments to the first rib, are an anomaly often associated with true neurogenic TOS. Some have suggested that too much significance has been placed on this finding because cervical ribs may be noted on up to 0.5% of routine radiographs. Furthermore, abnormal anatomy of the thoracic outlet—and in particular the presence of fibrous bands—is a common finding in the general population.² The congenital bands may arise from a cervical rib or from the transverse process of the seventh cervical vertebra, or they may be associated with the scalene muscles. These cervical bands and certain scalene muscle abnormalities appear to play an important part in the pathogenesis of neurogenic TOS.³

Clinical features

Paresthesias are common and follow the ulnar nerve distribution along the medial aspect of the arm and forearm and then distally to the fourth and fifth fingers. Aching pain radiating to the neck, shoulder, and arm is a frequent complaint and is often more diffuse than the paresthesias. Carrying heavy objects, persistent abduction of the shoulder, and work that requires overhead use of the arms may exacerbate these symptoms. TOS is also more likely to occur in individuals with poor posture and drooping shoulders.

Signs of motor weakness, if they appear, usually follow the sensory complaints. Patients may describe a feeling of weakness or clumsiness when using the hand. Wasting of the thenar, hypothenar, and intrinsic muscles of the hand is indicative of true neuropathic TOS.

A small number of patients have vasomotor disturbances, which may take the form of coldness, blanching, or cyanosis. In more extreme cases, trophic changes and even infarction of tissues at the fingertips may appear.⁴

Diagnosis

The most useful diagnostic approach to TOS is a careful physical examination, which may reveal tenderness over the brachial plexus, sensory deficits, motor weakness, or signs of muscle atrophy. Certain clinical stress tests have traditionally been used to diagnose TOS. The Adson, costoclavicular, and hyperabduction maneuvers (Figs. 81.2 to 81.4) are used. However, because these maneuvers are positive in the majority of normal individuals (a reduction in the radial pulse), they have diagnostic utility only when the patient's sensory symptoms are reproduced.

A radiograph of the cervicothoracic region may reveal a cervical rib or an elongated transverse process of C7, a clue to the presence of a fibrous band. The anatomy of the thoracic outlet can be well visualized with magnetic resonance imaging (MRI). Functional imaging can now be obtained with open-magnet MRI.⁵ With this technology one can assess compression of the brachial plexus by measuring the distance between the clavicle and first rib while the arm is in abduction.

Nerve conduction studies may be helpful in diagnosing true TOS but may not be revealing in disputed TOS. The differential diagnosis of disputed TOS should include other cervical lesions (tumors, disk disease, spondylosis) and reflex sympathetic dystrophy; in patients with vascular signs, other disorders of vessels should be considered (e.g., vasculitis and atherosclerosis).

Treatment

Initial management is conservative, especially when the symptoms are subjective, and consists of appropriate exercises designed to improve posture

TABLE 81.1 Peripheral entrapment neuropathies

	Nerve	Location/syndrome
Upper extremity and thorax	Brachial plexus	Thoracic outlet
	Dorsal scapular	Scalenus medius
	Suprascapular	Scapular notch
	Musculocutaneous	Elbow
	Radial	Posterior interosseous nerve syndrome
	Median	
	At elbow	Ligament of Struthers
	At forearm	Pronator teres
	At wrist	Carpal tunnel syndrome
	Anterior interosseous	Forearm
	Ulnar	
	At elbow	Cubital tunnel syndrome
	At wrist	Ulnar tunnel syndrome
Lower extremity	Obturator	Pelvis
	Sciatic	Piriformis syndrome
	Ilioinguinal	Lower part of abdomen
	Lateral femoral cutaneous	Meralgia paresthetica
	Femoral	Hip
	Peroneal	Fibular tunnel
	Saphenous	Hunter canal
	Sural	Lower part of leg
	Posterior tibial	Tarsal tunnel syndrome
	Interdigital plantar	Morton metatarsalgia

**Fig. 81.1** The three narrow channels of the outlet include the scalene triangle, the costoclavicular passage, and the pectoralis minor attachment at the coracoid process.

by strengthening the rhomboid and trapezius muscles. Avoidance of hyperabduction is important, and patients may have to consider changing occupation if their job requires prolonged use of their arms above the head.

It must be remembered, however, that carpal tunnel syndrome (CTS) may be manifested as pain radiating to the shoulder region and thus may be confused with TOS.⁶ Accordingly, distal nerve entrapment should be excluded before definitive therapy for TOS is considered.

Careful screening of patients is crucial before surgery since a large number of treatment failures have been reported in patients with the common or disputed forms of neurogenic TOS and because the brachial plexus is at risk for injury during surgery. Indications for surgery include true neurogenic TOS as evidenced by abnormal results on nerve conduction studies, intrinsic hand muscle atrophy, and the presence of a fibrous band or cervical rib, intermittent fleeting paresthesias replaced by continuous

**Fig. 81.2** The Adson maneuver. The patient inhales deeply, extends the neck fully, and turns the head to the side being examined. This tests for compression in the scalene triangle and is positive if the radial pulse diminishes and the patient's symptoms are reproduced.**Fig. 81.3** The costoclavicular maneuver. The patient takes an exaggerated military position of attention with the shoulders thrust backward and downward. A decreased radial pulse and reproduction of symptoms suggest neurovascular compression between the clavicle and first rib.

sensory loss, incapacitating pain, or worsening circulatory impairment (if present).³

Because it is often difficult to define the exact anatomic area of compression preoperatively, success rates of particular surgical procedures are, not surprisingly, quite variable. The transaxillary approach with first rib resection has many proponents. This method is useful for costoclavicular compression. Others prefer supraclavicular exploration with division of the scalenus anterior muscle and resection of the first rib.⁷ In either case, the surgeon must also search for constricting fibrous bands.

ULNAR NERVE COMPRESSION SYNDROMES

Cubital tunnel syndrome

Compression neuropathy of the ulnar nerve as it traverses the elbow has long been recognized as a complication of local trauma, particularly

Fig. 81.4 The hyperabduction maneuver. The patient lifts the hands above the head with the elbows somewhat flexed and extending out laterally from the body. This maneuver tests compression by the pectoralis minor at the coracoid process.

Fig. 81.5 The fibroosseous canal is formed by the medial epicondyle, the ulnar collateral ligament, and the flexor carpi ulnaris muscle. Elbow flexion decreases the volume of the channel.

fractures of the humerus. Only in recent years has the concept of constriction of the nerve in a fibroosseous tunnel been suggested.⁸

Anatomy

The osseous portion of the cubital tunnel is formed anteriorly by the medial epicondyle, laterally by the fibrous portion of the ulnohumeral ligaments, and posteromedially by the aponeurosis of the two heads of the flexor carpi ulnaris (Fig. 81.5). The size of the tunnel is reduced when the elbow is placed in flexion.

Etiology

Factors contributing to cubital tunnel syndrome include trauma, chronic pressure over the ulnar groove by occupational stress or unusual positioning of the elbow, synovitis, or osteophytes causing compression.

Clinical features

Paresthesias are noted in the distribution of the ulnar nerve, and in many instances the neuropathy is bilateral. The symptoms are often aggravated by prolonged use of the elbow in a flexed position. The Tinel sign may be positive over the ulnar groove, and pain may be provoked by placing pressure directly on the nerve, which may be noticeably swollen. A majority of patients will demonstrate atrophy of the intrinsic muscles and weakness in pinch and grasp. Wasting of the hypothenar muscles and slight clawing of the fourth and fifth fingers may be noted. A positive Wartenberg sign indicates weakness in adduction of the fifth finger.

Diagnosis

Consideration must be given to compression of the ulnar nerve at other locations, including the cervical spine, thoracic outlet, and Guyon canal (see later). Also, cubital tunnel syndrome must be differentiated from tardy ulnar palsy, in which neuropathy develops years after an injury.

Radiographs may be helpful in defining the cubital tunnel area and may reveal lesions such as osteophytes, which may impinge on the nerve. Electrodiagnostic studies are useful in establishing the site of ulnar compression and in monitoring recovery after treatment. The readily accessible location of the entrapment area allows direct testing of sensory and motor conduction across the cubital tunnel. High-resolution ultrasonography and MRI can accurately demonstrate ulnar nerve thickening as a result of entrapment.^{9,10}

Treatment

When the symptoms are primarily sensory and motor weakness is not marked, avoidance of prolonged elbow flexion may be sufficient. Compression resulting from inflammatory lesions, such as rheumatoid synovitis, may respond to local injection of corticosteroid along the ulnar groove while paying particular attention to avoid direct contact of the needle with the nerve.

In more advanced cases of cubital tunnel syndrome, a number of surgical procedures to decompress the nerve have been used, including simple release of the flexor carpi ulnaris aponeurosis, medial epicondylectomy, and anterior transposition of the nerve, the last being the most demanding operation. Simple decompression of the ulnar nerve is as effective as transposition and has fewer complications.¹¹ Because reinnervation of the nerve occurs slowly, in severe cases postsurgical recovery may take up to a year after a decompression procedure.

Ulnar tunnel syndrome

Ulnar tunnel syndrome results from entrapment of the ulnar nerve in the canal of Guyon at the wrist.¹² Many factors that affect the carpal tunnel can also influence the ulnar tunnel, which is in close proximity; at times, both areas are simultaneously involved.

Anatomy

The ulnar tunnel is bounded on the sides by the hook of the hamate and the pisiform bone. Above and below the tunnel are the volar and transverse carpal ligaments, respectively (Fig. 81.6). Inside the tunnel the ulnar nerve divides into sensory and motor branches.

Etiology

The most common cause of nerve compression in the canal of Guyon is a ganglion. Aberrant muscles, Dupuytren disease, rheumatoid arthritis (RA), and osteoarthritis may also cause impingement. Chronic trauma from the use of certain tools and occupations that require blows to the palm also predispose to ulnar tunnel syndrome.

Clinical features

When compression of the nerve occurs in the proximal portion of the ulnar tunnel, the patient will have combined sensory and motor deficits, hypoesthesia in the hypothenar region and fourth and fifth fingers (Fig. 81.7), and weakness of the intrinsic muscles of the hand. More distal lesions may be manifested as either motor or sensory impairment.

Diagnosis

Electrodiagnostic studies are helpful in determining the site of entrapment and in defining which branches are involved. Ulnar tunnel syndrome must be differentiated from TOS and CTS.

Treatment

If conservative measures such as avoidance of trauma to the palm do not result in improvement, surgical decompression may be necessary. When

Fig. 81.6 Because of the close relationship of the ulnar tunnel to the carpal tunnel, pathologic processes affecting one may simultaneously affect the other.

Fig. 81.7 The radial three digits and half of the ring finger are supplied by sensory branches of the median nerve. The fifth finger and half of the ring finger are supplied by sensory branches of the ulnar nerve.

entrapment is caused by ganglions, synovitis, or fibrosis, the offending tissue is excised.

MEDIAN NERVE COMPRESSION SYNDROMES (FOREARM ENTRAPMENT)

Anterior interosseous nerve syndrome

The anterior interosseous nerve (AIN) is a purely motor branch of the median nerve (Fig. 81.8). It innervates the pronator quadratus, the flexor pollicis longus, and the flexor digitorum profundus to the index finger. The nerve branches off from the median nerve about 6 cm below the lateral epicondyle. Entrapment may result from compression by aberrant or accessory muscles or fibrous bands beneath the pronator teres or by pressure from an enlarged bicipital bursa.

Fig. 81.8 The median nerve may be compressed at several locations in the forearm, most commonly as it traverses the pronator teres muscle. The anterior interosseous branch of the median nerve is solely motor; thus entrapment produces no sensory deficit.

Because the AIN does not have any sensory fibers, the patient has no sensory complaints and experiences only motor weakness. The typical pattern is loss of distal flexion of the thumb and index finger, which produces a characteristic pinch sign (Fig. 81.9). The pronator quadratus is tested with the elbow fully flexed. Resistance to forced supination of the forearm is decreased. The patient may also note a dull, aching pain in the volar aspect of the proximal part of the forearm.

Confirmation of AIN entrapment depends on electromyography (EMG) of the forearm muscles. Findings on MRI include increased signal intensity on T2-weighted or short tau inversion recovery sequences or atrophy of the innervated muscles (or both). The differential diagnosis for this syndrome should include rupture of the flexor pollicis longus tendon, which may occur with RA, and more proximal lesions such as brachial neuritis.

Because AIN syndrome improves with time in most patients, initial management is conservative unless the condition has been induced by a wound. The patient is advised to avoid repetitive forearm motion (pronation-supination). If the weakness does not resolve after 2 or 3 months, surgery is usually recommended.¹³

Pronator teres syndrome

The median nerve can become entrapped in the forearm at several potential sites (see Fig. 81.8). It may occur at the lacertus fibrosus, at the proximal edge of the flexor digitorum superficialis, or most commonly, by the pronator teres muscle itself or fibrous bands at the superficial head of this muscle.

The most consistent symptom in pronator teres syndrome is aching pain in the proximal part of the forearm, which often begins insidiously. The pain may be exacerbated by activities that require intensive use of the elbow, including pronation and grasping. Paresthesias are common and follow the median nerve distribution into the hand (see Fig. 81.7). Because the sensory

Fig. 81.9 Anterior interosseous nerve paralysis. The hand on the left demonstrates loss of function of the flexor pollicis longus and flexor digitorum profundus muscles, which results in a characteristic flattened pinch pattern.

findings are similar to those of CTS, the two conditions may be confused. However, unlike CTS, nocturnal paresthesias are less frequent in pronator teres syndrome.

Physical examination may reveal local tenderness on palpation over the pronator teres muscle. In addition, percussion in this area may elicit a positive Tinel sign with radiation of pain into the hand. A provocation test that may reproduce the pain involves pronation of the forearm and flexion of the wrist performed against resistance. Some thenar atrophy may be noted, but profound muscle weakness is rare.

In a study by Hartz and colleagues,¹⁴ electrophysiologic testing was often inconclusive and could not be relied on to exclude pronator teres syndrome. The differential diagnosis of pronator teres syndrome should include CTS and more proximal nerve lesions at the cervical spine or thoracic outlet. However, with thoracic outlet lesions the pain usually radiates into the ulnar rather than radial portion of the hand. There are few reports of effective imaging in this syndrome.

For some patients, sufficient treatment may be avoidance of provocative activities. Surgical decompression is performed when the symptoms become chronic.

CARPAL TUNNEL SYNDROME

CTS is the most common entrapment neuropathy. The syndrome has gained increased recognition in recent years because of the prominent attention that it has received in certain industrial settings, and it is now one of the most commonly reported occupational illnesses.

Anatomy

The carpal tunnel is bounded on its dorsal and lateral surfaces by the carpal bones and their connecting ligaments and on the volar or anterior aspect by the transverse carpal ligament (Fig. 81.10). Nine flexor tendons and the median nerve pass through the tunnel. The median nerve may become entrapped in two ways: pressure may be exerted on the nerve as a result of reduced capacity of the carpal tunnel, as occurs with swelling or lesions of surrounding tissues, or as a result of an increase in volume of the contents of the tunnel, an example being flexor tenosynovitis. Increased intracarpal canal pressure in patients with CTS has been confirmed by use of a wick catheter measuring device.¹⁵

Etiology

CTS has many causes (Table 81.2), but in some patients an underlying disease process cannot be identified and the designation “idiopathic CTS” is used. Because of increased awareness of certain occupational risk factors and the availability of sophisticated diagnostic techniques, an attributable cause of CTS can now often be found.

CTS is noted most commonly in persons whose occupations require substantial use of the hands. Workers who spend long hours using a keyboard, musicians who keep the wrist in a flexed position, and meat cutters are all especially susceptible to the development of CTS.

Fig. 81.10 The space for the median nerve and flexor tendons is very confined. The median nerve courses under the region occupied by the palmaris longus and flexor carpi radialis tendons.

Crystal-induced rheumatic disorders have been known to cause CTS. In the case of gout, tophaceous deposits or tenosynovitis may result in nerve entrapment. CTS is reported as a complication of several connective tissue diseases, including systemic sclerosis, polymyositis, polymyalgia rheumatica, and most commonly, RA. Indeed, prolonged median nerve sensory conduction velocities have been noted in up to 50% of all RA patients tested.¹⁶ Generally, CTS is a result of rheumatoid flexor tenosynovitis. When the symptoms are mild, it may be difficult to differentiate the muscle atrophy noted in CTS from that associated with severe rheumatoid disease.

Uremia also predisposes patients to entrapment neuropathy. CTS is particularly common in hemodialysis patients,¹⁷ and in many of these cases it is the result of β_2 -microglobulin amyloid deposition. A number of metabolic and endocrine diseases may have CTS as one of their manifestations, including diabetes, myxedema, mucopolysaccharidosis, and acromegaly.

Infections involving the carpal bones or flexor tendons at the wrist may result in CTS. Such infections include chronic granulomatous infections caused by *Coccidioides*, *Histoplasma*, *Mycobacterium tuberculosis*, and atypical mycobacteria.

Familial occurrence of CTS has also been reported. In one family the mean age at onset of CTS was 24 years, and flexor tenosynovitis was the dominant finding.¹⁸ The onset of symptoms in familial CTS may even occur in early childhood.

■ **TABLE 81.2** Conditions associated with carpal tunnel syndrome

	Mucopolysaccharidosis
Infection	Osteomyelitis (carpal bones)
	Tenosynovitis
	Tuberculosis
	Atypical mycobacterial infection
	Histoplasmosis
Iatrogenic	Coccidioidomycosis
	Hematoma
	Phlebitis
Miscellaneous conditions	Use of aromatase inhibitors
	Pregnancy
	Amyloidosis
	Dialysis
	Fractures

All varieties of amyloidosis—primary, secondary, hereditary, and associated with myeloma—may cause CTS. Lambird and Hartmann¹⁹ have shown that the transverse carpal ligament may appear grossly normal at the time of surgery and that if histologic stains for amyloid are not performed, the diagnosis of hereditary amyloidosis may be missed.

The development of CTS in pregnancy has been well documented. It has been attributed, by some, to fluid retention. In one series, 21% of pregnant women described paresthesias or hypoesthesia quite typical of CTS.²⁰ In the majority of patients, symptoms begin in the third trimester, usually resolve spontaneously after delivery, and do not require surgery.

A number of local space-occupying lesions may impinge on the contents of the carpal tunnel, including ganglions, hemangiomas, osteoid osteomas, and lipomas, as well as an anomalous median artery. Anomalous muscles may also compromise the carpal tunnel space. Most often this is caused by abnormalities of the palmaris longus, an extremely variable muscle that inserts on the transverse carpal ligament.²¹

Clinical features

Because the median nerve supplies sensory branches to the radial three fingers and half of the ring finger, these digits may have sensory loss with CTS (see Fig. 81.7). Typically, patients complain of burning, pins-and-needles sensations, numbness, and tingling in the fingers (Table 81.3). When questioned about the location of the paresthesias, many will indicate that the entire hand is involved. Only after careful examination does it become clear that the sensory abnormalities are limited to the area of the median nerve distribution.

In some cases pain may not follow the usual pattern of radiation in the median nerve distribution of the hand. Silver and colleagues²² found that 34% of patients with CTS also had signs of ulnar nerve compression. Proximal pain, often with a dull or aching quality, is also a common feature of CTS.⁶ Pain may radiate to the antecubital region or to the lateral shoulder area. Although the possibility of more proximal entrapment should be kept

in mind, the majority of patients experience improvement of symptoms after nerve decompression at the carpal tunnel.

Patients frequently complain of interruption of sleep because of paresthesias and often note that they shake their hands or run them under warm water to improve their symptoms.

Activities that result in persistent or repeated flexion or extension of the wrists are more likely to intensify the symptoms. Some patients report that they are more likely to drop objects, which they attribute to hand weakness. However, these individuals rarely have profound weakness on grip testing, and it is more likely that the problem stems from sensory deficit at the fingertips.

Tests

Testing for the Tinel sign consists of tapping lightly over the median nerve, and it is positive if the patient perceives paresthesia that radiates distally. Its diagnostic value depends largely on how the test is conducted. Mossman and Blau²³ found that to be effective, percussion must be performed with the patient's wrist in extension so that the carpal tunnel is compressed. They also noted that percussion with a fingertip or small neurology hammer is less effective than percussion with a broad-headed hammer, which can be used to percuss over the entire transverse carpal ligament and somewhat more proximally. The wrist flexion (Phalen) test is performed by having patients hold their wrists in extreme but unforced flexion for 1 minute. It is positive if the paresthesias are reproduced. As with the Tinel sign, the wrist flexion test is not invariably positive for CTS, but when it is, it helps substantiate the diagnosis.

Another provocative test for CTS is the carpal compression test, in which pressure is applied directly over the carpal tunnel and the underlying median nerve. Opinions are conflicting on whether it is more sensitive or specific than the Tinel or Phalen test. When compared with the "gold standard" of electrophysiologic testing, the carpal compression test appears to have only marginal predictive value.²⁴

To determine motor loss, the strength of the thenar muscles should be tested. The easiest muscle to test is the abductor pollicis brevis. With the thumb first adducted toward the fifth finger, the patient is asked to abduct against resistance to the distal phalanx. The opponens pollicis muscle is tested by having the patient touch the tip of the thumb to the tip of the fifth finger, and then the examiner attempts to break the pinch. Inspection of the hand may reveal atrophy of the thenar muscles (Fig. 81.11).

Fig. 81.11 Thenar muscle atrophy. Chronic entrapment of the median nerve in the carpal tunnel or more proximally may produce thenar atrophy.

Diagnosis

Diagnosis of CTS is based on the patient's history and clinical examination, but imaging and electrodiagnostic studies may be useful in confirming the diagnostic impression. Conventional radiographs using a carpal tunnel projection can help delineate the soft tissues and carpal bones. Increasingly, ultrasonography has been found to be very effective in diagnosing CTS.²⁵ Typically, it reveals swelling of the median nerve in the proximal end of the tunnel and flattening more distally. Some have even suggested that it should be the study of first choice, even before electrodiagnostic testing.²⁶ However, the anatomy of the carpal tunnel, thickening of the flexor tendon sheaths, or the presence of space-occupying lesions or aberrant muscle can be better visualized with MRI.²⁷

The most important electrodiagnostic study is measurement of sensory nerve conduction velocity (NCV) across the carpal tunnel. Slowed NCV, along with prolongation of distal motor latency, lends support to the diagnosis of CTS.

In about 15% of the population, fibers from the median nerve travel via the ulnar nerve to the thenar muscles: the Martin Gruber anastomosis. It is important to recognize this entity because it may result in sparing of the thenar muscles in patients with CTS. A clue to the presence of this anatomic variation is the finding of normal proximal latency but prolonged distal latency.

The differential diagnosis of CTS must include median nerve entrapment proximal to the carpal tunnel.⁴ As noted earlier, compression of the median nerve near the elbow, as found in pronator teres syndrome, may yield similar sensory findings.

Treatment

Specific treatment of CTS depends, to a large degree, on whether a cause of the entrapment can be identified. Conservative measures may suffice when the symptoms are of short duration. EMG repeated over time may help the clinician determine the correct therapeutic approach. Patients with progressive increases in distal motor latency times should be considered for surgery.

Splinting

Splinting is a simple and cost-effective modality that if successful in relieving the symptoms, helps confirm the diagnosis of CTS. Because wrist motion often worsens CTS, splinting is an important treatment element. A volar wrist splint that keeps the wrist in a neutral position is particularly helpful during the night, when the wrist often falls into a position of flexion. Splinting alone may be sufficient to relieve CTS, primarily in cases in which the symptoms are of recent onset.

Local injection of corticosteroid

Injection of corticosteroid into the carpal tunnel is another effective treatment in individuals whose disease is of shorter duration and who have no significant muscle wasting. The best response to injection occurs in patients whose symptoms have been present for less than 1 year and who have no significant muscle atrophy or weakness. A recent randomized, controlled trial that compared local corticosteroid injection with surgical decompression found that over the short term, injection provided better relief and was equal to surgery in alleviating symptoms at 1 year.²⁸

Before injection is attempted, certain landmarks should be identified, including the tendons of the palmaris longus and flexor carpi radialis

muscles. This is most easily accomplished by asking the patient to flex against resistance. Injection can be facilitated if the wrist is placed in slight extension. The needle is inserted ulnar (medial) to the palmaris longus tendon and proximal to the wrist crease. If the patient notes median nerve paresthesia during the injection, the needle should be withdrawn and repositioned to avoid injury to the nerve. Frequent injections are proscribed because of the danger of tendon rupture. Evidence for the use of ultrasound-guided techniques for injection of the carpal tunnel is increasing.^{29,30}

Nonsteroidal antiinflammatory drugs and other agents

The use of nonsteroidal antiinflammatory drugs (NSAIDs) is generally limited to patients with an underlying inflammatory lesion, such as tenosynovitis. Oral corticosteroids also appear to be an effective treatment of mild to moderate CTS.

Surgery

Surgical release of the transverse carpal ligament is the definitive treatment of more severe cases of CTS. Surgery is indicated when the response to conservative measures is inadequate, in patients with progressive or persistent neurologic changes, or when muscle atrophy is present. In patients with marked tenosynovitis, such as occurs with RA or granulomatous disease, simple decompression of the carpal tunnel may not be sufficient; additional tenosynovectomy with lysis of adhesions may be necessary. Furthermore, when infiltrating processes are present, such as amyloid deposits attached to tendons, the more complicated procedure of tenolysis may be necessary. Because tuberculosis and fungal infections are sometimes a cause of CTS, appropriate cultures and histologic studies should be undertaken at the time of surgery, particularly if tenosynovitis is noted. The traditional surgical approach of ligament sectioning via a palmar incision is increasingly being replaced by endoscopic release. However, this is controversial among hand surgeons because of the lack of strong evidence supporting this newer technique.³¹ Though equally effective, it must be performed with great care to avoid injury to the superficial palmar arterial arch or to the median or ulnar nerves.³²

Failure of surgery to relieve the symptoms is often the result of incomplete release of the ligament. Postoperative improvement depends in part on the severity of the initial nerve deficit. Although most patients' symptoms are ameliorated by surgery, individuals whose occupations require repetitive motion may need to be retrained for less hand-intensive work.

RADIAL NERVE COMPRESSION SYNDROME

Posterior interosseous nerve syndrome

Posterior interosseous nerve (PIN) syndrome is a well-recognized, but uncommon entity caused by compression of the radial nerve. The most common site of compression is at the level of the supinator muscle.³³

Anatomy

The radial nerve comes off the posterior branch of the brachial plexus (C5 through C8, T1), and it branches proximal to the lateral epicondyle into a superficial sensory branch and a deep motor branch. The deep motor branch pierces the supinator muscle and courses along the dorsal aspect of the interosseous membrane. The deep motor branch is called the *posterior interosseous nerve*.

Etiology

PIN syndrome can be caused by intrinsic as well as extrinsic lesions. Trauma, inflammatory processes such as RA, and space-occupying lesions may be causative.³⁴

Clinical features

Patients with PIN syndrome usually complain of forearm pain. Other patients describe weakness of the extensor muscles. If entrapment occurs at the level of the supinator, the radial wrist extensors innervated at this level will be spared because they branch off proximal to the PIN. Complete sparing of the extensor carpi radialis longus and frequent sparing of the extensor carpi radialis brevis occurs because they, too, branch off proximal to the PIN. As a result, the ulnar wrist extensors and the extensors of the metacarpophalangeal joints will be compromised. With attempted wrist extension, the wrist deviates radially in PIN syndrome. Because the extensor muscles of the fingers are affected, it is difficult to maintain the fingers in extension. PIN syndrome is not associated with any reflex or sensory loss.

PIRIFORMIS MUSCLE AND SCIATIC NERVE, POSTERIOR VIEWS

Fig. 81.12 The piriformis muscle arises from the anterior surface of the sacrum and the gluteal surface of the ilium and crosses the greater sciatic foramen to insert onto the superior border of the greater trochanter. (a) In most instances the sciatic nerve passes along the anterior surface of the piriformis muscle and exits the pelvis below the piriformis muscle while passing posteriorly along its inferior border. (b) In some individuals a portion of the sciatic nerve passes through the piriformis muscle. Other anatomic variants have been described.

Diagnosis

The differential diagnosis of PIN syndrome includes lateral epicondylitis and other chronic pain syndromes in the region of the elbow and forearm. Other diagnoses to consider in patients with wristdrop and fingerdrop include a central lesion or one in the posterior cord of the brachial plexus. Electrodiagnostic and imaging studies are useful in confirming the diagnosis of PIN syndrome and differentiating it from other causes.^{35,36}

Treatment

Treatment of PIN syndrome usually consists of conservative measures. Modalities such as splinting can be used. In patients whose symptoms do not resolve with conservative management, surgery is an option. PIN syndrome that results from compression by a tumor should be treated surgically.

PIRIFORMIS SYNDROME

Piriformis syndrome results from compression of the sciatic nerve by the piriformis muscle. This syndrome, though relatively uncommon and underdiagnosed, nevertheless accounts for a discrete portion of patients with buttock and sciatic-type pain.

Anatomy

As the sciatic nerve passes through the greater sciatic foramen, it is in close proximity to the piriformis muscle (Fig. 81.12). The muscle originates from the anterior surface of the sacrum and the gluteal surface of the ilium. After passing through the sciatic foramen, it inserts on the medial aspect of the greater trochanter. Usually, the sciatic nerve passes below the piriformis muscle, but in some cases a segment of the nerve or the entire nerve passes through the muscle.

Etiology

The leading cause of piriformis syndrome is thought to be trauma to the gluteal region with resultant inflammation and spasm of the muscle. This in turn leads to irritation of the sciatic nerve. When the nerve or a portion of the nerve passes through the muscle, nerve compression can occur with stretching of the muscle on internal hip rotation.

Clinical features

Typically, patients with piriformis syndrome complain of pain in the buttock region with radiation to the posterior aspect of the thigh. However, discomfort and paresthesias may occur along the entire course of the sciatic nerve. Pain may be induced by prolonged sitting or by stooping and lifting.

On physical examination, pain may be elicited by applying direct pressure over the gluteal region. Also, piriformis muscle tenderness or spasm may be noted on rectal or pelvic examination. Maneuvers that internally rotate, flex, and adduct the hip often cause aggravation of the pain because such motion stretches the piriformis muscle. With the patient seated, resisted abduction of the hip (the Pace sign) may also elicit pain.

Diagnosis

Included in the differential diagnosis of piriformis syndrome are conditions that result in sciatic nerve irritation, such as a herniated lumbar disk, spinal stenosis, or a pelvic lesion, but it is unusual for patients with piriformis syndrome to have neurologic defects. Thus, the diagnosis is often one of exclusion.

MRI is useful in detecting changes in the piriformis muscle and in defining its relationship to the sciatic nerve.³⁶ It is also a means of excluding mass lesions in the pelvic area, as well as spinal stenosis and disk herniation.

Treatment

Initial management of piriformis syndrome consists of conservative measures, including physical therapy, analgesics, and NSAIDs. Injection of corticosteroid or botulinum toxin directly into the piriformis muscle appears to benefit some patients.³⁷ Patients who do not respond to conservative therapy may be candidates for surgical intervention. The piriformis is released from its insertion on the femur to allow reattachment in a shortened position.³⁸

MERALGIA PARESTHETICA

The term *meralgia* has its roots in the Greek words for thigh (*meros*) and a painful condition (*algia*). Meralgia paresthetica is caused by entrapment of the lateral femoral cutaneous nerve. One of the earliest descriptions of this entity was by Sigmund Freud, who related the typical symptoms of meralgia paresthetica that he experienced.³⁹ Although meralgia paresthetica occurs primarily in adults, children may be affected, and there is often a significant delay in diagnosis.⁴⁰

Anatomy

The lateral femoral cutaneous nerve is entirely sensory and arises from the second and third lumbar roots. It proceeds from the lateral border of the psoas muscle, along the ilium, and passes under or through the lateral aspect of the inguinal ligament just medial to the anterior superior iliac spine, the most common site of entrapment (Fig. 81.13). The nerve travels down the anterior aspect of the thigh, where it divides into anterior and posterior branches. These branches supply sensation to the anterolateral portion of the thigh.

Etiology

Direct pressure from belts and other tight-fitting garments may contribute to entrapment of the nerve as it passes under the inguinal ligament. Workers who support heavy bundles on their thigh are also at risk. Several clinical conditions have been associated with the development of meralgia paresthetica, including obesity, pregnancy, diabetes, ascites, and trauma to the thigh or inguinal region. The neuropathy may also occur as a consequence of direct injury to the nerve during surgery in the pelvic region (e.g., appendectomy, inguinal herniorrhaphy, iliac bone procurement, bariatric surgery).

Clinical features

Patients with meralgia paresthetica typically complain of burning pain and dysesthesia in the sensory distribution of the nerve. However, a smaller area of sensory deficit is common. The patient may volunteer that certain positions seem to exacerbate the discomfort, such as sitting with the legs crossed, prolonged standing, or extending the leg posteriorly.

Fig. 81.13 The potential for entrapment of the lateral femoral cutaneous nerve can be seen by its course just under the inguinal ligament and medial to the anterior superior iliac spine.

Diagnosis

In the differential diagnosis of meralgia paresthetica it is important to consider the possibility that radiculopathy of the L2 or L3 nerve roots or spinal stenosis may be causing the symptoms. Some patients will report direct tenderness over the inguinal ligament.

Electrodiagnosis using superficial electrodes to measure NCV may be useful in confirming the diagnosis. Nerve block may also affirm the diagnosis in addition to offering pain relief.

Treatment

Because meralgia paresthetica is often self-limited, conservative measures should be used, possibly including weight reduction, elimination of occupational trauma, and avoidance of external mechanical pressure over the inguinal ligament. Local injection of anesthetic and corticosteroid may be useful, as may be NSAIDs.

If meralgia paresthetica becomes chronic and the pain unremitting, surgical decompression (neurolysis) or transection of the nerve may be considered.⁴¹ When it is of spinal origin, epidural corticosteroid injection may be helpful.

PERONEAL NERVE ENTRAPMENT

Anatomy

The common peroneal nerve (also known as the common fibular nerve) is derived from the dorsal branches of the fourth and fifth lumbar and the first and second sacral nerves. It descends obliquely along the lateral side of the popliteal fossa to the head of the fibula, close to the medial margin of the biceps femoris muscle. It lies between the tendon of the biceps femoris and the lateral head of the gastrocnemius muscle, winds around the neck of the fibula between the peroneus longus and the bone, and divides beneath the muscle into the superficial peroneal nerve and the deep peroneal nerve. It innervates the peroneus longus, peroneus brevis, and the short head of the biceps femoris muscle.

Etiology and clinical features

Compression of the common peroneal nerve occurs most commonly just below the knee as the nerve wraps around the lateral aspect of the fibula. It is usually caused by external pressure on the nerve, as during prolonged periods of lying down such as after surgery or prolonged hospitalization. Crossing the legs, squatting, and leg casts can also cause compression at this site. Occasionally, injury can occur in the popliteal fossa secondary to compression from a Baker cyst. Lipomas and ganglion cysts can also be factors in causing compressive symptoms. Several recent case series have looked at the relationship between significant weight loss and peroneal neuropathies in populations with cancer or anorexia nervosa and after bariatric surgery.⁴²⁻⁴⁴ Typically, patients have footdrop or a high-stepping gait to compensate for the inability to dorsiflex the affected foot. Patients may also complain of paresthesias and occasionally sensory loss over the dorsum of the foot and lateral aspect of the shin. The deep peroneal nerve can be injured in the region of the ankle as a result of a tight-fitting rim or strap from a shoe. Patients generally complain of pain in the region with minimal weakness and sensory disturbance involving only the web space between digits 1 and 2.

Diagnosis

On physical examination, patients are often unable to dorsiflex and evert the foot. Sensory disturbance is confined to the dorsum of the foot, including the web space between digits 1 and 2, and the lateral aspect of the shin. Reflexes are normal. EMG and NCV studies are very useful for identifying peroneal neuropathy at the fibular neck; conduction block may be identified on peroneal motor studies. Increasingly, ultrasound and MRI are being used as the imaging modalities of choice for peroneal neuropathies.⁴⁵⁻⁴⁷

Treatment

In patients with a peroneal neuropathy at the fibular neck, measures that reduce pressure, such as extra cushioning while sleeping and avoidance of crossing the legs during the day, are usually sufficient to alleviate the symptoms. An ankle-foot orthosis splint to keep the foot dorsiflexed should be used until active movement has recovered. Physical therapy consisting of active and passive range-of-motion exercises, as well as walking, is an important conservative measure. Surgical decompression can be considered for patients who do not recover on their own with the aforementioned measures.

TARSAL TUNNEL SYNDROME

Tarsal tunnel syndrome undoubtedly occurs more frequent than suggested by the isolated reports in the literature.⁴⁸ It is often mistaken for other disorders of the foot, and clinicians are less likely to include this entrapment neuropathy in the differential diagnosis of foot pain (see Chapter 78).

Anatomy

The tarsal tunnel is a fibroosseous canal formed by the flexor retinaculum (lacinate ligament) as it extends from the medial malleolus down onto the calcaneus (Fig. 81.14). The posterior tibial nerve passes through the tunnel along with vascular structures, tendons of the flexor hallucis longus, and the flexor digitorum longus muscle. Along its course the tibial nerve gives off calcaneal branches and then lateral and medial plantar branches (see Fig. 81.14). The calcaneal branches are solely sensory, but the plantar nerves have mixed motor and sensory function. Because the narrowest aspect of

Fig. 81.14 Entrapment of branches of the posterior tibial nerve occurs under the flexor retinaculum, which attaches to the medial malleolus. Because the posterior tibial nerve has calcaneal and medial and lateral plantar branches, symptoms of entrapment will depend on which branches are affected.

the tunnel is the distal or anteroinferior portion, the plantar nerve branches are most likely to be entrapped at this location.

Etiology

A number of abnormalities have been reported to cause tarsal tunnel syndrome, including bone deformity after fractures, pressure from casts, hypertrophy of the lacinate ligament or the abductor hallucis muscle, flexor tenosynovitis, synovial cysts, ganglion cysts, and diabetes mellitus. The proliferative synovitis accompanying RA is also causative.

Clinical features

The signs and symptoms of tarsal tunnel syndrome depend on the level of stenosis and consequently on which branches of the posterior tibial nerve are involved. The patient usually complains of burning pain or paresthesias in the toes, sole, or heel of the foot. As with CTS, pain may awaken the patient at night and may move in a retrograde fashion to the calf. Relief may be obtained by walking. Commonly, direct palpation over the nerve posterior to the medial malleolus elicits tenderness, and a fusiform swelling may be present in this region. Other findings can include a positive Tinel sign over the tarsal tunnel, vasomotor changes, and weakness of toe flexion and the intrinsic muscles of the foot.

Diagnosis

The differential diagnosis for tarsal tunnel syndrome includes arthritis of the tarsal bones, plantar fasciitis, vascular insufficiency, and systemic peripheral neuropathy. Tarsal tunnel syndrome may also be confused with lumbosacral nerve root radiculopathy. Another differential condition, particularly in runners, is hypertrophy of the abductor hallucis muscle; however, in this case, compression of the plantar nerve occurs distal to the lacinate ligament.

Electrodiagnostic studies are useful in confirming the diagnosis of tarsal tunnel syndrome. NCV is often diminished, and there may be abnormalities in distal motor latencies. Prolonged distal motor latencies of the plantar nerves may occur in 25% of patients with RA. MRI is the best method for demonstrating the anatomy of the tarsal tunnel and thus for detecting space-occupying lesions.

Treatment

A number of conservative therapies have been used for tarsal tunnel syndrome, including local injection of corticosteroid, NSAIDs, and orthotics, none of which have consistently been effective. The standard treatment is surgical decompression, which gives excellent results in the majority of patients.⁴⁹ If the patient's symptoms are the result of pressure on the nerve from the abductor hallucis muscle, release of the muscle at its origin is performed rather than sectioning of the flexor retinaculum.

MORTON METATARSALGIA (MORTON NEUROMA, INTERDIGITAL NEURITIS)

Entrapment neuropathy of the interdigital plantar nerves occurs most commonly in the web space between the third and fourth toes, but it may also affect other interspaces. Chronic irritation of the nerve may lead to the development of a neuroma (see Chapter 78).

Anatomy

The medial and lateral plantar nerves of the foot divide into digital nerves in the web spaces between the toes. These interdigital nerves lie on the plantar side of the transverse metatarsal ligament (Fig. 81.15). Between the metatarsal joints are bursae that project distally and are close to the neurovascular bundle.

Etiology

Because the interdigital nerves are on the plantar side of the transverse metatarsal ligament, entrapment as a result of compression between the metatarsal heads, as originally proposed by Morton, is highly unlikely. It is more probable that the taut ligament itself is the cause of the entrapment. In addition, there is evidence that the intermetatarsal bursae may also impinge on the nerve directly or, when inflamed, cause metatarsalgia. Wearing tight-fitting or high-heeled shoes also tends to aggravate the condition, which may explain why women are affected more often.

Fig. 81.15 On the plantar surface of the foot the interdigital nerve is compressed below the transverse metatarsal ligament and not between the metatarsal heads (plantar view).

Clinical features

Typically, patients complain of an aching or burning pain that radiates from the web space distally to the affected toes. Activities such as jogging or long periods of standing may worsen the metatarsalgia, as does walking on hard surfaces. Direct pressure applied over the interspace between the metatarsal bones often elicits tenderness, and occasionally a painful nodule may be palpated.

Diagnosis

Morton metatarsalgia must be differentiated from inflammatory conditions affecting the forefoot. RA may be manifested as metatarsalgia, but in most cases examination reveals synovitis, and neuritic pain is uncommon. Conventional radiographs are of little value in diagnosing Morton neuroma but may demonstrate other causes of forefoot pain such as exostosis or fracture. Ultrasonography can identify neuromas, which appear as ovoid, hypoechoic lesions. MRI is very effective in identifying and localizing neuromas. Interestingly, lesions consistent with neuroma may be found in 33% of asymptomatic individuals.⁵⁰

Treatment

Initial treatment should include conservative measures such as padding the metatarsal area and the use of broad-toed shoes. Benefit has also been reported to be derived from injection of local anesthetic and corticosteroids.

When conservative treatment fails, the traditional approach has been surgical resection of the neuroma. The clear drawback with this procedure is that the patient is left with a sensory deficit. Another strategy is release of the transverse metatarsal ligament and epineural neurolysis of the interdigital nerve.⁵¹ This method avoids neurectomy while decompressing the nerve.

COMPARTMENT SYNDROMES

Compartment syndromes can be defined as an increase in tissue pressure within a confined space or muscle compartment that compromises the local circulation and neurologic function.

Acute compartment syndrome

Acute compartment syndrome is a surgical emergency that can result from a direct blow to the muscle, from the trauma associated with a fracture, or from prolonged pressure over a muscle compartment. It also occurs rarely

Fig. 81.16 The muscles of the leg are contained within four compartments separated by deep transverse fascia.

after prolonged exertion. Acute compartment syndromes can lead to rapid and complete muscle necrosis as a result of vascular compromise. Early surgical decompression of the compartment may allow restoration of circulation to the muscle and preserve function. The clinical diagnosis of acute compartment syndrome should be suspected in patients who have pain that is out of proportion to the injury or a history of injury, swelling and firmness of the muscle compartment, and pain on passive stretch. Later in the evolution of acute compartment syndrome, signs of decreased perfusion develop, including decreased pulses, reduced capillary refill, and skin pallor. Neurologic symptoms may also appear.

Chronic compartment syndrome

This is the typical form seen in athletes and is characterized by return to normal function between episodes of exercise-induced pain. It most commonly occurs in the lower part of the leg.

The muscles of the leg are contained within four compartments separated by deep transverse fasciae (Fig. 81.16). The athlete describes aching or cramping of the leg, roughly in the distribution of the involved compartment. The period from commencement of exercise to the onset of symptoms is variable and depends on the type and intensity of exercise but is usually within 10 to 30 minutes. Return to normal is also variable, within minutes in most cases, but in more severe cases complete resolution can occasionally take hours. Neurologic symptoms may occur because of ischemia of nerves, particularly in anterior tibial syndrome.

No diagnostic signs occur during rest, which makes the diagnosis difficult and dependent on a good history. However, fascial defects may be found with MRI in up to 40% of patients. After sufficient exercise, tenderness and fullness will be noted in the muscle compartment involved, most commonly the anterolateral compartment.

Slit catheter measurement of intracompartmental pressure before and after exercise can be used to select patients suitable for surgical decompression, provided that it is performed in a specialized center with reliable standardization.⁵² However, the significance of a mild elevation in pressure in some patients remains controversial. It is likely that MRI will prove to be of increasing importance in diagnosis, along with the development of more sophisticated imaging techniques involving biochemical shifts or pH changes.⁵³

Compartment syndrome of the forearm is much less common but may particularly be seen in weight lifters and rowers. The deep fascia of the forearm encloses both the flexor and extensor muscles, which are separated by the radius, ulna, and interosseus membrane. The deep flexor compartment of the forearm is the more common site of involvement.

Complex regional pain syndrome

■ RACHEL GORODKIN

DEFINITION

- *Complex regional pain syndrome* (CRPS) is a pain disorder that can develop after injury to a limb.
- There are no diagnostic tests for CRPS; the diagnosis is made on the basis of specific symptoms and signs.

CLINICAL FEATURES

- There is usually a preceding noxious event or period of immobilization, although in 10% of cases there is no clear precipitating event.
- The most characteristic feature is spontaneous pain, which usually begins in an extremity and then extends proximally and is disproportionate to the initiating event.
- Edema, vasomotor abnormalities (color and temperature), sudomotor abnormalities (changes in sweating), and motor and trophic changes are common but variable features.
- Radiographs of the affected extremity may show patchy osteoporosis, which is most marked in the juxtaarticular region.

HISTORY AND TERMINOLOGY

In 1864, Mitchell and colleagues¹ described what we now recognize as complex regional pain syndrome (CRPS) when reporting the complications of peripheral nerve injuries caused by gunshot wounds sustained by soldiers during the American Civil War. The old term *reflex sympathetic dystrophy* was first used by Evans in the mid-1940s.² Since then, many terms, some of which are listed in [Box 82.1](#), have been used to describe the painful swelling of an extremity that is usually associated with a preceding injury. This multiplicity of terms has been confusing, and in recent years considerable effort has been invested in clarifying the definition and terminology for this condition, with the descriptive term *complex regional pain syndrome* coming into usage in 1995.³

CRPS type I (*without* preceding nerve injury) equates to what was previously termed *reflex sympathetic dystrophy*, and CRPS type II (*with* preceding nerve injury, usually traumatic) is what was previously termed *causalgia*. Therefore the problems that Mitchell and colleagues described in soldiers would now more accurately be called *CRPS type II*. Although the distinction between the two subtypes can be made, there is currently no evidence that it affects outcome.

DIAGNOSIS AND CLINICAL FEATURES

CRPS is primarily a clinical diagnosis and is often difficult to make. The current diagnostic criteria are known as the *Budapest criteria*⁴ ([Box 82.2](#)) and rely purely on symptoms and signs, so the clinician needs to be familiar with these. In addition to varying among patients, clinical features vary within an individual patient over time. Almost invariably, it is an extremity that is affected. Hand and wrist, knee, or foot and ankle are most commonly involved, although an entire limb can become affected, as shown in [Fig. 82.1](#). Usually only one limb is affected, but the condition may be bilateral or another limb may become affected at a later date.⁵

Both symptoms and signs are grouped under four headings, which are considered in turn: sensory, vasomotor, sudomotor/edema, and motor/trophic. These features are summarized in [Table 82.1](#).

Sensory

The most characteristic feature of CRPS is severe, persistent pain, which often has a burning quality. The pain is different in character from that of the injury that precipitated the CRPS and, although usually beginning in the extremity, frequently extends proximally in a nondermatomal pattern. On examination, the affected site is diffusely tender, often with allodynia and hyperalgesia. These are separate phenomena: *allodynia* is pain that is provoked by a stimulus that is not normally painful, whereas *hyperalgesia* is an exaggerated response to a painful stimulus. *Hyperpathia* is also observed in patients with CRPS (especially those with later disease) and can be defined as an increased response to a repetitive stimulus. It is being increasingly recognized that patients with CRPS may also experience disturbances in body perception.⁶

Vasomotor

The patient may complain of changes in skin color or temperature in the affected extremity, which are revealed on clinical examination by comparison with the unaffected side. A temperature difference of at least 1°C is counted as significant and coincides with the minimum that can easily be picked up by clinical examination. Typically, the affected limb is initially warm and red and may then become mottled and intermittently warm and cool before becoming more permanently cold and cyanotic. However, not all patients pass through these three phases (see later). It has been suggested that patients who report early coldness are at high risk of going on to develop severe, late-stage disease, with infection, ulcers, chronic edema, dystonia, and myoclonus.⁷

Sudomotor/edema

Swelling of the affected extremity is common, especially in the early phase ([Fig. 82.2](#)), and may be associated with increased or reduced sweating.

Motor/trophic

The patient may describe inability to initiate movement, weakness (although this is difficult to assess in the presence of severe pain), tremor, or muscle spasms. Sometimes there are dystonic features.⁸ Hair growth and nail changes are commonly seen, and the skin may become atrophic and shiny. Contractures can occur in late-stage disease ([Fig. 82.3](#)).

EPIDEMIOLOGY

There is little accurate data on either the incidence or prevalence of CRPS. However, it is clear that minor forms are not rare. Some investigators have reported, in prospective studies, a cumulative incidence of around 30% after Colles or tibial fractures,⁹ although others reported an incidence as low as 1%.¹⁰ Fortunately, only a minority of patients progress to late-stage disease (see later). A recent study in the Netherlands estimated the overall incidence rate to be 26.2 per 100,000 person-years, with the highest incidence in the 61- to 70-year age group.¹¹ However, CRPS can occur in persons of any age and is well recognized in children.¹² It has been reported more frequently in women than in men with a ratio of 3.5:1.^{11,13,14}

BOX 82.1 TERMS USED IN THE DEFINITION OF COMPLEX REGIONAL PAIN SYNDROME

Complex regional pain syndrome (CRPS) type I (the preferred term)
 Causalgia (now CRPS type II)
 Reflex sympathetic dystrophy (RSD)
 Sudeck atrophy
 Shoulder-hand syndrome
 Algodystrophy
 Algoneurodystrophy
 Posttraumatic dystrophy
 Posttraumatic osteoporosis
 Painful osteoporosis
 Transient osteoporosis

Some terms are listed that are or have been used to describe what is now considered under the definition of CRPS.

BOX 82.2 CRITERIA FOR THE DIAGNOSIS OF COMPLEX REGIONAL PAIN SYNDROME TYPE I

1. Continuing pain disproportionate to the inciting event
2. At least one sign in two or more categories
3. At least one symptom in three or more categories
4. No other condition present that could explain the symptoms and signs

Categories

- A. **Sensory:** allodynia, hyperalgesia, hyperesthesia (symptom only)
 B. **Vasomotor:** temperature asymmetry (at least 1°C), skin color asymmetry, skin color changes
 C. **Sudomotor/edema:** edema, changes or asymmetry in sweating
 D. **Motor/trophic:** decreased range of motion, motor dysfunction (weakness, tremor, dystonia), trophic changes (hair, nails, skin)

Adapted from Harden RN, Bruhl S, Stanton-Hicks M, Wilson PR. Proposed new diagnostic criteria for complex regional pain syndrome. *Pain Med* 2007;8:326-31.

Fig. 82.1 Complex regional pain syndrome affecting the lower limb, which shows marked swelling and color change. (Reproduced with permission from Salford Royal NHS Foundation Trust.)

Triggers

A variety of triggers can precipitate CRPS (Table 82.2). The most common causes are peripheral trauma (fracture or soft tissue injury) and orthopedic surgery. CRPS can also develop after central nervous system or spinal disorders and rarely after visceral lesions such as myocardial infarction. Up to 10% of patients have no identifiable causative event.^{13,14} Immobilizing a limb (for any reason) is likely to be a significant predisposing factor: in one large study, 47% of subjects had undergone a period of limb immobilization before diagnosis.¹³

Personality traits

Patients with CRPS are often extremely distressed by their pain, and it has been suggested that certain personality traits are associated with CRPS, but there is no convincing evidence to support this hypothesis.¹⁵ It seems likely that the pain behavior that undoubtedly develops in a proportion of patients is a consequence of, rather than a predisposing factor for, their CRPS.

TABLE 82.1**Clinical features of complex regional pain syndrome**

Sensory	Pain, often burning, extending beyond the area of the original injury Allodynia Hyperalgesia/hyperpathia Disturbed body perception
Vasomotor	Color change* Temperature change*
Sudomotor/edema	Edema Increased sweating
Motor/trophic	Weakness/inability to initiate movement Tremor Muscle spasms Dystonic features Contractures Skin, hair, and nail changes

*Compared with the unaffected side.

Fig. 82.2 Early complex regional pain syndrome of the left hand and wrist, which show edema. (Reproduced with permission from Salford Royal NHS Foundation Trust.)

NATURAL HISTORY

The clinical course of CRPS has been divided into three stages. Although there is some doubt as to the clinical usefulness of this subdivision, it may be of help when considering studies of pathophysiology and treatment. The three stages are as follows:

Fig. 82.3 Complex regional pain syndrome (CRPS) of the ankle and foot. (a) Well-established CRPS of the right ankle and foot, showing contracture. (b) The extent of deformity associated with CRPS is well demonstrated radiographically. The affected foot is osteoporotic. (Reproduced with permission from Salford Royal NHS Foundation Trust.)

TABLE 82.2
Typical triggering events for complex regional pain syndrome

Trauma	Wrist fractures Tibial fractures Soft tissue injuries
Surgery	Carpal tunnel decompression Arthroscopy Lumbar spine surgery
Central nervous system or spinal disorders	Head injury Hemiplegia
Visceral lesions	Myocardial infarction

Stage 1: acute. The limb may be either warm or cool, with edema.¹³
Stage 2: dystrophic. The limb becomes cooler, and either mottled or cyanotic, with early dystrophic changes of the skin and nails.
Stage 3: atrophic. During this stage, the pain spreads proximally (in some patients the limb may become less painful) and there are irreversible atrophic changes and contracture. In some patients ankylosis can occur.

The duration of each of these three stages is highly variable, and patients may exhibit features of more than one stage simultaneously.¹⁶ Many patients never progress beyond stage 1.
The vast majority of patients with CRPS experience a single episode, with only 2% experiencing a relapse.¹³

DIFFERENTIAL DIAGNOSIS

The differential diagnosis, at least in the early stages of CRPS, is that of the causes of a tender, often swollen limb. Inflammatory arthritis, cellulitis, osteomyelitis, deep vein thrombosis, malignancy, and fracture might all be suspected, but careful history taking should point to the diagnosis, especially when there is a history of a prior trauma. Neuropathic pain disorders also enter into the differential diagnosis. Chronic vascular insufficiency and thoracic outlet syndrome must be considered in the differential diagnosis of late-stage CRPS.

INVESTIGATIONS

There is no diagnostic test for CRPS. However, certain investigations may give supportive evidence. Blood tests should all yield normal results.

Fig. 82.4 Complex regional pain syndrome of the wrist seen (a) at the time of the initial injury and (b) after 3 months, with patchy osteoporosis apparent. (Reproduced with permission from Central Manchester University Hospitals NHS Foundation Trust.)

Plain radiography

The characteristic radiographic findings of CRPS are well described. The typical appearance is of patchy osteoporosis of the affected extremity. This is most marked in the juxtaarticular region (Fig. 82.4) but can be more diffuse.¹⁷ Soft tissue swelling is often present, at least in early disease. The joint space is usually preserved, although in patients who progress to late-stage disease there may be loss of joint space and ankylosis.

Isotope bone scanning

Traditionally, isotope bone scanning (especially three-phase imaging) was considered useful in the diagnosis of CRPS to seek asymmetry between affected and nonaffected limbs, although the actual abnormality depends on disease stage. Thus there is increased uptake in early disease (Fig. 82.5) and reduced uptake in later disease.¹⁸ However, there has been some skepticism as to the true usefulness of isotope bone scanning,¹⁴ and many specialist units rarely use it.

Magnetic resonance imaging

Appearances on magnetic resonance imaging tend to be nonspecific and include soft tissue changes and bone marrow edema.¹⁹ At present, magnetic resonance imaging is not considered part of the routine diagnostic evaluation of CRPS but is often useful if the diagnosis is uncertain.

Other investigations

A number of other investigations have been used primarily on a research basis. These include measurement of surface temperature using thermography (Fig. 82.6),²⁰ quantitative sweat testing (using the quantitative

sudomotor axon reflex test), quantitative sensory testing (testing small fiber function), sympathetic skin response (which measures skin conductance),²¹ and psychological tests.

PATHOLOGIC FEATURES

The pathologic features of CRPS are not well described, which reflects the reluctance to subject affected limbs to biopsy for fear of exacerbating the clinical problem. A pathologic study of skeletal muscle and peripheral nerve tissue from lower limb amputations from eight patients revealed muscle changes consisting of type I fiber atrophy, an increase in lipofuscin (suggestive of free radical-mediated injury), and capillary abnormalities, with thickening or duplication of the basement membrane.²² There were no consistent abnormalities in peripheral nerves. The authors postulated that a microangiopathy was central to pathophysiology. In contrast to the lack of tissues from deeper structures, there is a relative wealth of data from skin biopsies. The largest study looked at biopsy specimens from 43 patients but found no difference in epidermal nerve fiber density or sweat gland nerve fiber density between patients and control subjects.²³

PATHOPHYSIOLOGY

The pathophysiology of CRPS is not fully understood. It is unknown why some patients, after only a minor injury, go on to develop CRPS, whereas most make an uncomplicated recovery. Many different theories have been suggested.^{16,21,24-28} It seems most likely that both peripheral and central mechanisms are involved, interacting to maintain a vicious cycle of events, the end result of which is the persisting pain of CRPS with its accompanying vasomotor, sudomotor, and trophic changes. Inflammatory changes and microcirculatory dysfunction, possibly resulting in oxidant stress, have also been proposed as important mechanisms of tissue injury, as has immune dysfunction. It seems probable that these different aspects of pathophysiology are all interrelated (Fig. 82.7).

Peripheral mechanisms

Peripheral nerve damage

It is likely that trauma to type C nerve fibers and A δ afferents is an initiating event in the CRPS process, and at least some patients go on to demonstrate sensitization of their C or A δ nociceptors in the context of thermal and mechanical hyperalgesia.¹⁶ Although localized small fiber nerve damage precipitated by trauma would fit many of the features of CRPS, this is not consistently borne out in skin biopsy studies.²³

Sympathetic dysregulation

It was originally thought that abnormality of the sympathetic nervous system was a key component in the pathogenesis of CRPS. Although this is no longer generally accepted, there is no doubt that a select group of patients have an element of sympathetically maintained pain,²⁴ as demonstrated by their response to sympathetic blockade.

Fig. 82.5 Isotope bone scan showing diffuse increased uptake in the distal tibia, talus, and navicular in a patient with complex regional pain syndrome of the left ankle and foot. (Reproduced with permission from Salford Royal NHS Foundation Trust.)

Fig. 82.6 Thermographic images. (a) A patient with complex regional pain syndrome (CRPS) of the left hand (same patient as in Fig. 82.2). The affected hand is cooler: the temperature difference between the dorsum of the left hand and the dorsum of the right hand is 3.4°C. (b) A patient with CRPS of the left knee. The affected knee is cooler: the temperature difference between the left and right knees is 1.9°C. (Reproduced with permission from Salford Royal NHS Foundation Trust.)

Fig. 82.7 Central, peripheral, and neurogenic mechanisms have been proposed for complex regional pain syndrome (CRPS).

Sympathetic activity may activate both mechanoreceptors and nociceptors and could therefore contribute to the vicious cycle involving central mechanisms (see later). α -Adrenoreceptors may be overexpressed in hyperalgesic skin of patients with CRPS and may then be activated through sympathetic discharge.²⁴ Some patients experience pain relief from α -adrenergic blockade with intravenous phentolamine, but the situation is complex, with several studies suggesting a reduction in sympathetic efferent activity leading to supersensitivity to catecholamines.^{29,30} Despite these pointers toward a role for the sympathetic nervous system, a systematic review of clinical trials using regional guanethidine sympathetic blocks found no effect,³¹ and the current consensus is that sympathetic dysregulation plays only a minor role in the pathophysiology of CRPS.

Neurogenic inflammation

There is considerable evidence to suggest that neurogenic inflammation contributes to the pathogenesis of CRPS.²⁶ This might explain why some of the early clinical features of CRPS are inflammatory.¹³ Release from afferent nerve fibers of vasoactive peptides, including substance P and calcitonin gene-related peptide, causes vasodilation with increased vascular permeability and protein leakage, and also increases the excitability of primary sensory nerve fibers, which leads to changes in the dorsal horn.

Microvascular dysfunction

It is not known whether the vascular changes in CRPS drive the disease process by causing hypoxia and free radical-mediated damage or whether they are secondary. A number of investigators have confirmed microvascular dysfunction in CRPS,^{29,30} and hypoxia has been directly demonstrated in CRPS-affected limbs.³² Relevant to this is that vitamin C, a powerful antioxidant, may prevent the development of CRPS,³³ and free radical scavengers may have a beneficial effect in the treatment of CRPS.³⁴

Central mechanisms

Central sensitization

It has been suggested that, in CRPS, an initial activation of nociceptors leads to alteration of central information processes, resulting in central sensitization. This disordered processing of nociceptor impulses may be the most important mechanism of persisting pain in late-stage CRPS—activation of low-threshold mechanoreceptors is interpreted as noxious and so causes allodynia. A role for the *N*-methyl-D-aspartate (NMDA) receptor has been suggested¹⁶ and is borne out by recent trials looking at the use of intravenous ketamine (an NMDA antagonist).³⁵ Inhibitory neurons using γ -aminobutyric acid (GABAergic) may also play a part, as indicated by improvement in dystonia in response to baclofen (a GABA receptor agonist).³⁶

Cortical reorganization

There is increasing interest in the role that abnormal cortical processing plays in CRPS, with motor and sensory cortical reorganization demonstrated via various techniques including magnetoencephalography and functional magnetic resonance imaging.²⁷ Graded motor imagery³⁷ (thought-based exercises designed to train the brain) and mirror therapy³⁸ (physical exercises using a mirror to hide the affected limb and visually trick the brain into seeing two normally functioning limbs) have both been demonstrated

TABLE 82.3

Approaches to the treatment of complex regional pain syndrome

Prevention	Early mobilization Vitamin C
Physiotherapy	Desensitization techniques Mirror therapy Graded motor imagery Transcutaneous electrical nerve stimulation Acupuncture
Drug treatment	Possibly effective (although no large-scale studies) Bisphosphonates Free radical scavengers (dimethyl sulfoxide [topical] and <i>N</i> -acetylcysteine) Ketamine (intravenous) Insufficient evidence for effectiveness Analgesics (including paracetamol, nonsteroidal antiinflammatory drugs, and opioids) Anticonvulsants Antidepressants Baclofen (oral and intrathecal) Botulinum toxin (intramuscular) Calcitonin Calcium channel blockers Capsaicin Corticosteroids Lidocaine 5% plasters
Spinal cord stimulation	
Surgery (very rarely indicated)	Surgical sympathectomy Amputation

to be helpful, although the mechanism by which they exert their effect is unclear.

Other mechanisms

Autoimmunity

Antineuronal antibodies have been found in patients with CRPS, and infusion of patient immunoglobulin into mice produces abnormal behavior. There has been recent interest in the effect of a single infusion of low-dose (0.5 g/kg) intravenous immunoglobulin. Pain relief has been demonstrated in a subgroup of patients, but the numbers tested remain very small at present.²⁸

Genetics

Various HLA associations have been tested for, but there has been no overall consensus on a single area of interest.

Summary

Our current state of knowledge regarding the pathophysiology of CRPS can be summed up as follows: the condition is most likely initiated by a peripheral injury causing subclinical nerve damage and neurogenic inflammation, and possibly also altering immune system function. Initial changes are mediated by nociceptive A δ and C fibers, leading to sensitization and release of inflammatory neuropeptides at the dorsal horn ganglion and abnormal connections with the sympathetic nervous system, potentially resulting in sympathetically maintained pain. Dysfunction within the spinal cord can extend to adjacent levels and can cross the midline, leading to spread within a limb and contralateral symptoms. Later changes include long-term alterations in neuropeptide production, abnormalities of both excitatory and inhibitory spinal and supraspinal pathways, and motor and sensory cortical reorganization. Both early and late changes cause abnormalities of blood flow, which may themselves be responsible for some of the features of CRPS.

MANAGEMENT

There are a number of treatment options in CRPS, which are summarized in Table 82.3.

Although many patients with mild forms of CRPS may experience spontaneous improvement, those who progress to a late stage with atrophy and

contracture are very unlikely to recover. These patients are left with pain and major functional disability. Therefore early diagnosis is a key principle of management.

In addition to being a condition that is difficult to diagnose and treat, CRPS is difficult to study because of its heterogeneity, the problems in definition referred to earlier, a lack of outcome measures,³⁹ and the incomplete understanding of its pathophysiology. As a result, until very recently there have been very few controlled clinical trials,^{40,41} and those that do exist tend to be in small numbers of patients, with subjective endpoints. Many of the recommendations about treatment (including those considered here) are based on anecdotal observations or small series of patients.

The treatment of CRPS should be multidisciplinary. Many of the patients demonstrate marked pain behavior, and their distress may be compounded by the fact that, before diagnosis, their pain was thought to be “nonorganic.” Patient education and an approach based on a biopsychosocial model of pain management are integral to treatment. Although there are no randomized controlled trials of cognitive-behavioral therapy in CRPS, it is appropriate to refer patients for psychological input if they appear distressed or are slow to improve. Medications and interventions are discussed later, but given the overall lack of CRPS-specific evidence, drugs given are usually those with support for their use in patients with other types of neuropathic pain.

Prevention

Ideally, the development of CRPS should be prevented by early mobilization of patients with predisposing conditions and careful attention to surgical technique. A recent study of 300 patients undergoing surgery for Dupuytren contracture suggested that anesthetic technique was also likely to influence outcome.⁴² As stated earlier, it has been suggested that vitamin C (500 mg/day), a powerful antioxidant, may prevent the development of CRPS,³⁸ the rationale being that oxidant stress contributes to pathophysiology. Although potentially very exciting, this observation requires confirmation in further studies.

There is very little evidence regarding secondary prevention in patients with CRPS who need to undergo surgery. A common sense approach is to try and defer surgery until the CRPS symptoms are well controlled.

Physiotherapy and occupational therapy

Physiotherapy alone may correct mild cases of CRPS. In more advanced disease, severe pain is a barrier to rehabilitation, and physiotherapy is used in parallel with medical and psychological approaches. In a randomized trial in patients with upper limb CRPS, both physiotherapy and occupational therapy conferred benefit in terms of pain reduction and functional improvement.⁴³ An algorithm for therapy, with an emphasis on the rehabilitative aspects, has been put forward by Stanton-Hicks and coworkers.⁴⁴ Mirror therapy is now relatively widely used because it is a very simple and safe technique to apply, although it is most effective if implemented very early in the course of the condition.⁴⁵ Graded motor imagery has also been increasingly used, but it requires a significant time commitment from the patient, and unpublished clinical audits from several centers have not been able to reproduce the degree of effectiveness seen in Moseley's original paper.³⁷

Physiotherapists may also try modalities such as transcutaneous nerve stimulation and acupuncture, but there are no good-quality studies as yet to support their use.

Drug treatment

A very large number of drugs have been suggested for the treatment of CRPS (see Table 82.3), but, to reemphasize what was stated earlier, few have been shown to be effective in randomized clinical trials. Even when good-quality trials have been carried out, the numbers of patients are almost invariably small.^{40,41} Usually the first-line pharmacologic intervention is with analgesics and nonsteroidal antiinflammatory drugs. Because most patients have a significant element of neuropathic pain, a reasonable next step is to

commence neuropathic analgesics such as tricyclic antidepressants and anti-epileptics. However, there are no CRPS-specific trials to back up this recommendation, and the little evidence there is suggests that gabapentin is not effective at a dose of 1800 mg/day.⁴⁶

Several papers have been published on the use of bisphosphonates reporting generally positive results. For example, alendronate has been shown to reduce pain and improve function,^{45,47} but dosages used have varied widely, ranging from 35 mg per week to 40 mg daily.

Ketamine at subanesthetic doses blocks NMDA receptors and therefore reduces the excitatory effect of glutamate on the central nervous system; benefit has been reported in two small randomized, controlled trials,^{35,48} but most regimens require a 5- to 10-day hospital admission for relatively short periods of relief.

Lidocaine 5% patches show promise,⁴⁹ if only for the way they protect allodynic skin from contact with clothing. Small studies have also shown benefit from early use of corticosteroids and use of antioxidant agents such as *N*-acetylcysteine and dimethylsulfoxide.³⁴

Sympathetic blockade

In the past, sympathetic blockade has been recommended as a treatment for CRPS, and a good response to this treatment has been considered an aid to diagnosis. However, guanethidine regional blockade has been shown to be ineffective in meta-analyses,³¹ and this procedure is falling out of use, although it may continue to be a helpful intervention in a small subgroup of patients. Local anesthetic sympathetic blockades are also ineffective.⁵⁰

Other treatments

Spinal cord stimulation has been shown to be effective in reducing pain (but not in improving function) in patients with well-established CRPS, although its effectiveness decreases over time.⁵¹ Because the procedure is not without risk, patients must be carefully selected.

A small proportion of patients come to surgical treatment. Rarely, surgical sympathectomy has been advocated if a patient gains benefit from temporary sympathetic blocks. Amputation is not recommended for pain alone, because phantom limb pain at the amputation stump may result, but it may be indicated, for example, if a limb is persistently infected.

Future therapies

Recent years have seen a huge expansion in research interest in CRPS, with the result that better classification criteria (lack of which was a major stumbling block to earlier research) and better outcome measures are being developed, which will facilitate clinical trials of new treatments.³⁹ Development of new therapies will, in turn, be directed by advances in understanding of pathophysiology and may include vasoactive, antioxidant, and immunomodulatory treatments in addition to different forms of analgesia such as NMDA antagonists.

CONCLUSION

CRPS remains a condition that is difficult to diagnose, to treat, and to study. However, it is a major source of pain and disability in that subgroup of patients who go on to develop severe, late disease. The rheumatologist's task is to maintain a high index of suspicion of CRPS in a patient with a painful extremity and to institute treatment, including mobilization, early in an attempt to prevent progression to late disease. Ideally, patients with CRPS should be cared for by an experienced multidisciplinary team.

Acknowledgments

The author would like to acknowledge the contribution of Professor Ariane Herrick, who was coauthor of this chapter in the previous edition.

RHEUMATOID ARTHRITIS AND
OTHER SYNOVIAL DISORDERS

83

Classification and epidemiology
of rheumatoid arthritis

■ KATHERINE P. LIAO ■ ELIZABETH W. KARLSON

- Rheumatoid arthritis (RA) has an annual incidence of approximately 0.4 per 1000 in females and 0.2 per 1000 in males; recent evidence indicates that the incidence may be rising.
- A prevalence of 0.4% to 1% is reported in diverse populations worldwide with evidence for geographic variation.
- Cigarette smoking remains the strongest environmental risk factor for RA; other lifestyle factors and exposures such as alcohol use may be inversely associated with RA.
- Childhood and current low socioeconomic status are associated with increased risk of RA.
- Hormonal and reproductive factors contribute to the female predominance in RA; parity, breastfeeding, and exogenous hormones are modifiers of RA risk in women.

CLASSIFICATION OF RHEUMATOID ARTHRITIS

Rheumatoid arthritis (RA) typically manifests clinically as symmetric inflammation of the small joints in the hands and feet. However, few patients are textbook cases, and studying the disease requires a uniform definition with high sensitivity and specificity that is valid across institutions and countries as well as over time. The 2010 RA classification criteria, developed collaboratively by the American College of Rheumatology (ACR) and the European League Against Rheumatism (EULAR), are the current standard for disease classification.¹ These new criteria replaced the 1987 ACR classification criteria, which up until recently were the gold standard for case definition in the majority of RA clinical studies.² It is important that rheumatologists remain acquainted with the 1987 criteria because many of the epidemiologic studies used this criteria set until 2010.

The 1987 ACR criteria for the classification of RA, designed for application in clinical research studies only and not for diagnosis, were developed from data for individuals diagnosed with RA by their rheumatologists (mean duration of symptoms, 7.7 years).² Members of the classification committee employed expert opinion and consensus to determine the final seven clinical characteristics they believed were important in determining RA status. Validation studies conducted in the outpatient clinics confirmed that the criteria were an accurate method of classifying RA with a sensitivity in the range of 77% to 95% and specificity in the range of 85% to 98%.³ Due to the nature of the training cohort from which the criteria were developed, the criteria perform best at distinguishing individuals with long-duration and active RA from individuals with other arthritides.

The 2010 update in the RA classification criteria (Table 83.1) reflects advancements in the diagnosis and treatment of RA since 1987. Antibodies to citrullinated proteins (ACPs) were found to be a more specific biomarker for early RA than rheumatoid factor (RF) (specificity of ACPs ranged from 94% to 100% compared with 23% to 96% for RF) with

sensitivity comparable to that of RF.^{4,5} Of equal import, more recent studies have demonstrated that early aggressive treatment of RA can halt or slow the progression of synovitis and bone erosions, decreasing disease-related disability and increasing the rate of remission.⁶⁻⁸ This led to strong interest in detecting the disease earlier in the clinical setting and identifying patients with early disease for research studies. However, the 1987 ACR criteria did not perform as well in classifying early RA (in studies, defined as the presence of arthritis symptoms for 4 weeks to 2 years) as in identifying longer-duration RA. The presence of ACPs was not part of the 1987 ACR criteria, and other criteria, such as joint erosions and rheumatoid nodules, are not often found in early RA and are outcomes rheumatologists seek to prevent.

The goal of the 2010 ACR/EULAR criteria was to create a method for RA classification *de novo* using rigorous methodology by employing both a data-driven and a consensus-driven approach. These criteria were designed primarily for RA classification for research studies, but in contrast to the 1987 ACR criteria can also be used for diagnosis. Development of the 2010 ACR/EULAR criteria occurred in three phases. Phase 1 used data from nine early arthritis cohorts across Europe and Canada to identify important domains and clinical variables that define RA. Phase 2 engaged an international panel of expert clinicians to score abstracted real-life clinical cases for probability of RA. Information from their scoring was used to extract the clinical information deemed important for ruling in or out RA. The final phase incorporated information from both the data-driven and the consensus-driven segments to determine the specific clinical factors to be included in the 2010 RA classification criteria (see Table 83.1). The notable differences between the 2010 and 1987 criteria are the following: First, synovitis was redefined as active synovitis in at least one joint that cannot be better explained by another diagnosis. Second, positivity for ACPs and abnormal levels of the inflammatory markers erythrocyte sedimentation rate and C-reactive protein level were added as criteria, whereas morning stiffness, rheumatoid nodules, and erosions or periarticular osteopenia on radiographs were removed. Thus far, validation studies have demonstrated that the 2010 criteria perform well, classifying RA patients earlier in the course of the disease than the 1987 criteria with comparable sensitivity and specificity.^{9,10}

DISEASE OCCURRENCE

Determining the precise incidence and prevalence of RA can be challenging. An ideal of study of RA incidence would include continual surveillance of a stable population over time. Because of the low incidence of the disease, only a few studies have been conducted with adequate sample size and follow-up to provide statistically precise estimates. An ideal study of prevalence should include all past and inactive cases of a disease in a population (and hence provide a measure of lifetime cumulative prevalence). RA is a disease that after onset can follow varying clinical courses, including progression, stable disease with or without flares, or remission. For a study to recognize remitted disease requires the use of criteria specifically designed for this purpose. It is often difficult to establish the extent to which remitted disease has been included in published reports.

TABLE 83.1
2010 ACR/EULAR criteria for rheumatoid arthritis (RA)

Target population (those who should be tested): Patients	
1. who have at least 1 joint with definite clinical synovitis (swelling) ^a	
2. whose synovitis is not better explained by another disease ^b	
Classification criteria for RA (score-based algorithm: add score of categories A to D; a score of $\geq 6/10$ is needed to classify a patient as having definite RA) ^c	
A. Joint involvement^d	Score
1 large joint ^e	0
2-10 large joints	1
1-3 small joints (with or without involvement of large joints) ^f	2
4-10 small joints (with or without involvement of large joints)	3
>10 joints (at least 1 small joint) ^g	5
B. Serologic results (at least 1 test result is needed for classification)^h	
Negative RF and negative ACPA	0
Low-positive RF or low-positive ACPA	2
High-positive RF or high-positive ACPA	3
C. Acute-phase reactants (at least 1 test result is needed for classification)ⁱ	
Normal CRP and normal ESR	0
Abnormal CRP or abnormal ESR	1
D. Duration of symptoms^j	
<6 wk	0
≥ 6 wk	1

^aThe criteria are aimed at classification of newly presenting patients. In addition, patients with erosive disease typical of RA with a history compatible with prior fulfillment of the 2010 criteria should be classified as having RA. Patients with long-standing disease, including those whose disease is inactive (with or without treatment) who, based on retrospectively available data, have previously fulfilled the 2010 criteria should be classified as having RA.

^bDifferential diagnoses vary among patients with different presentations but may include conditions such as systemic lupus erythematosus, psoriatic arthritis, and gout. If it is unclear about the relevant differential diagnoses to consider, an expert rheumatologist should be consulted.

^cAlthough patients with a score of <6/10 are not classifiable as having RA, their status can be reassessed and the criteria might be fulfilled cumulatively over time.

^dJoint involvement refers to any swollen or tender joint on examination, which may be confirmed by imaging evidence of synovitis. Distal interphalangeal joints, first carpometacarpal joints, and first metatarsophalangeal joints are excluded from assessment. Categories of joint distribution are classified according to the location and number of involved joints, with placement into the highest category possible based on the pattern of joint involvement. "Large joints" refers to shoulders, elbows, hips, knees, and ankles.

^e"Small joints" refers to the metacarpophalangeal joints, proximal interphalangeal joints, second through fifth metatarsophalangeal joints, thumb interphalangeal joints, and wrists.

^fIn this category, at least 1 of the involved joints must be a small joint; the other joints can include any combination of large and additional small joints, as well as other joints not specifically listed elsewhere (temporomandibular, acromioclavicular, sternoclavicular, etc.).

^g"Negative" refers to international unit (IU) values that are less than or equal to the upper limit of normal (ULN) for the laboratory and assay; "low-positive" refers to IU values that are higher than the ULN but ≤ 3 times the ULN for the laboratory and assay. Where RF information is available only as positive or negative, a positive result should be scored as low-positive for RF.

^hNormal/abnormal is determined by local laboratory standards.

ⁱ"Duration of symptoms" refers to patient self-report of the duration of signs or symptoms of synovitis (e.g., pain, swelling, tenderness) of joints that are clinically involved at the time of assessment, regardless of treatment status.

ACPA, anti-citrullinated protein antibody; ACR, American College of Rheumatology; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; EULAR, European League Against Rheumatism; RF, rheumatoid factor.

From Aletaha D, Neogi T, Silman AJ, et al. 2010 Rheumatoid arthritis classification criteria: an American College of Rheumatology/European League Against Rheumatism collaborative initiative. *Arthritis Rheum* 2010;62:2569-81, Table 3.

Direct comparisons of published data of RA occurrence are problematic because of the need to take into account differences in the sensitivity and specificity of criteria sets used at the time of the study, such as the 1958 American Rheumatism Association (ARA) criteria, the 1987 ACR criteria, and now the 2010 ACR/EULAR criteria. There is now evidence that the severity of RA may be declining and the disease may be entering remission earlier after treatment.¹¹ Hence older prevalence estimates may be less relevant to the contemporary pattern of disease occurrence.

Incidence

Since a number of methods have been used to classify RA, incidence and prevalence rates are not directly comparable across studies. Overall,

incidence rates are higher in northern Europe and North America than in southern Europe (Table 83.2) based on a review of studies using the 1987 ACR criteria.¹² The median observed incidence was 29 cases per 100,000 (range, 24 to 36), in northern Europe, 38 (range, 31 to 45) in North America, and 16.5 (range, 9 to 24) in southern Europe.¹²

Prevalence

There have been a number of contemporary studies of the prevalence of RA based on large-scale cross-sectional population samples. Estimates using the 1987 ACR criteria conducted in various populations worldwide are listed in Table 83.3.¹² Because the 2010 RA criteria were recently published, there are no studies to date using the most recent criteria. Estimates using past criteria sets are listed in Table 83.4. Most studies show a female-male excess of between 2:1 and 3:1. In all studies, age-specific prevalence rates increase with age.

In the United States, the lifetime risk of RA, interpreted as the percentage of individuals who develop RA at any age, is 3.6% for women and 1.7% for men.¹³ These estimates were determined based on incidence rates in a population-based RA cohort in Rochester, Minnesota, from 1997 to 2007 and age- and sex-specific mortality rates for the United States for the year 2000.

Geographic variation

Overall, the majority of estimates of RA prevalence worldwide based on 1987 ACR criteria range between 0.4% and 1% (see Tables 83.3 and 83.4). Northern Europe and North America had higher prevalence rates than the rest of the world, ranging from 0.4% to 1%. Southern Europe had lower prevalence rates, ranging from 0.3% to 0.7%. The two studies from the Middle East suggest that prevalence rates in that region are similar to the rate in the northern countries. Prevalence rates in Africa and Asia tended to be lower, with the majority ranging between 0.2% and 0.3%, with higher rates in urban areas. Particularly high prevalence rates of RA have been found in certain Native American groups, including the Pima, Yakima, and Chippewa. This excess is not seen in other Native Americans, such as the Blackfoot and Haida.

Time trends

Two studies that used the 1987 ACR criteria examined trends in the incidence of RA since 1995 and reported an increase in this period, particularly in women, in the United States and Denmark.^{14,15} However, more data are needed to determine whether this represents a true increase in the overall incidence of RA. This increase follows decades of decline in the incidence in RA reported by several studies. In the Pima Indian population, the incidence of RA was observed to have halved in both males and females in the 25 years between 1965 and 1990.¹⁶ Data from a study in the United States in which similar methods of case ascertainment have been in place for 40 years confirm a decline in incidence from 0.61 per 1000 in 1955-1964 to 0.33 per 1000 in 1985-1994.¹⁷ The decrease was greatest in females. The declining incidence was also seen through successive birth cohorts. Updated RA incidence data from a population in the United States show a striking cyclical variation in the rate from year to year, which suggests the possibility of specific risk factors acting at different points in time (Fig. 83.1).

The severity of RA may also be declining over time. In an analysis of the features of disease severity in successive birth cohorts of patients, one study showed that there was a peak in erosive, seropositive, and nodular disease in individuals diagnosed with RA in the 1960s but a decline in the severity of disease in subsequent generations.¹⁸ A decline in prevalence of RF seropositivity has also been reported among younger birth cohorts in the Pima Indian population.¹⁹ However, this trend has not been seen in U.S. data,¹⁷ which show no evidence that the proportion of patients with RF seropositivity or erosive change has diminished over time. The mortality from RA also remained constant over the 40-year period of observation.

ENVIRONMENTAL FACTORS

Lifestyle factors

Cigarette smoking, a modifiable risk factor, remains the strongest known environmental risk factor for RA.^{20,21} Since this association was first discovered over a decade ago, subsequent studies have elucidated the nature of this association.²² We now know that smoking is most strongly associated with ACPA-positive and RF-positive RA.^{23,24} The risk of RA increases with

the intensity (packs per day) and duration of cigarette use.^{25,26} An individual's risk can remain elevated for up to 20 years after smoking cessation²⁵; however, it does decrease with time since quitting.²¹ Among blacks, the increased risk of RA associated with smoking was found to be limited to heavy smokers (defined as 10 pack-years or longer) in one cohort.²⁷ The population excess risk due to smoking is estimated to be 35%.^{25,28}

Carrying RA risk alleles in the human leukocyte antigen shared epitope (HLA-SE), the strongest genetic risk factor for RA, modifies the risk of RA in smokers, which suggests a gene-environment interaction.^{29,30} Studies show gene-environment interaction in analyses of ever smokers compared with never smokers in predicting seropositive (ACPA+ or RF+) RA, with

stronger interactions in analyses comparing never or light smokers with heavier smokers (10 pack-years or more), which suggests a dose response for smoking.^{25,31,32} This gene-environment interaction between smoking, the shared epitope, and increased risk of ACPA+ RA forms a potential model for the cause of RA.²⁹ Smoking increases the proportion of citrulline-positive cells in the lungs (demonstrated to occur by analysis of bronchoalveolar lavage fluid in smokers and absent in nonsmokers). Individuals with the shared epitope may be genetically predisposed to develop ACPAs, which places them at higher risk of developing RA.

There is evidence suggesting that other genes may also have significant interactions with cigarette smoke to increase risk for RA.³² These include

Fig. 83.1 Annual incidence of rheumatoid arthritis (RA) per 1000 population in Rochester, Minnesota, between 1955 and 2007. (From Myasoedova E, Crowson CS, Kremers HM, Therneau TM, Gabriel SE. Is the incidence of rheumatoid arthritis rising? Results from Olmsted County, Minnesota, 1955-2007. *Arthritis Rheum* 2010;62:1576-82, Fig. 1.)

specific polymorphisms of genes encoding enzymes that detoxify carcinogens, glutathione S-transferase genes and the heme oxygenase 1 gene (HMOX1) among whites.^{33,34} Among blacks, an interaction between heavy smoking and the N-acetyltransferase 2 (NAT2) loci was observed.³⁵

Alcohol consumption may also lower the risk of developing RA, particularly ACPA+ RA.²⁴ A dose-dependent effect was also observed whereby individuals with the highest consumption (five or more drinks or 80 g ethanol per week) had a decreased risk of RA on the order of 40% to 50% compared to those with low to no consumption (less than 0.5 g ethanol per

week).³⁶ Coffee consumption has also been implicated as a risk factor for seropositive RA in longitudinal data from Finland,²² as has consumption of decaffeinated coffee in the United States³⁷; however, neither of these associations was replicated in a subsequent study.³⁸

The evidence linking obesity to increased risk of RA is conflicting. Obesity, defined as a body mass index of 30 or higher, was found to be associated with RA risk in population-based case-control studies with odds ratios ranging from 1.4 to 3.7.^{39,40} However, no association was observed in follow-up studies with prospective cohort designs.^{41,42} The most recent study conducted using a population-based case-control design found an association between individuals with a body mass index of 30 or higher and RA risk (odds ratio, 1.6; 95% confidence interval, 1.0 to 3.3) in ACPA+ women only.⁴³ This association was not observed in men with RA or ACPA+ women.

Nutrition

Studies of dietary influences on risk of RA have also produced conflicting results. Consumption of olive oil and fish oil has been reported to protect against the risk of developing RA; however, this association could not be confirmed in a prospective cohort study.⁴⁴ High protein and red meat intake was found to increase the risk of inflammatory arthropathy,⁴⁵ but a subsequent study showed no association with protein, iron, or red meat consumption and the risk of developing RA.⁴⁶

Vitamin D is an important modulator of the inflammatory response through the vitamin D receptor⁴⁷ in addition to playing a role in bone and mineral homeostasis. Lower intake of vitamin D was associated with an increased risk of RA in one study,⁴⁸ but no association was observed in another prospective study.⁴⁹ In a study assessing vitamin D levels before RA diagnosis, there was no difference in vitamin D levels measured at 1 year, 2 years, or 5 or more years before diagnosis.⁵⁰ Diets high in vitamin C were associated with a reduced risk of inflammatory polyarthritis in the United Kingdom⁵¹; however, an antioxidant protective effect was not observed in a large prospective cohort study based in the United States.⁵² There is also some evidence that copper and selenium deficiency are linked with RA.⁵³

Medications

The hydroxymethylglutaryl-coenzyme A reductase inhibitors (statins) have modest antiinflammatory effects in both RA cases and patients without rheumatic disease.^{54,55} Recent studies suggest that statin use may also reduce risk of RA by approximately 40% in individuals with hyperlipidemia.^{56,57}

Infectious agents

Classic epidemiologic evidence of an infectious cause for RA has not been forthcoming. Incident cases of RA do not cluster in space or time.⁵⁸ Concordant monozygotic twins, sibling pairs, and spouse couples show very little similarity in the timing of disease onset. Overcrowding as assessed by sibship size also has not been found to be a risk factor.

Potential associations with infectious agents have been observed, although the data are often conflicting. Increased titers of antibodies to the Epstein-Barr virus (EBV) have been demonstrated in RA patients after diagnosis. Titers were also shown to be increased before disease onset in a small group of patients in one longitudinal study⁵⁹; however, a subsequent longitudinal study found no difference in EBV titers in pre-RA cases and controls.⁶⁰ Antibodies to human parvovirus B19 were also found to be increased in females with RA in one case-control study.⁶¹ In general, it is conceivable that increased autoantibody concentrations may be a reflection of the disease process rather than infection prior to onset of disease. Serologic data have yielded no conclusive evidence of association with a number of other putative infectious triggers, including *Proteus*, cytomegalovirus, retroviruses, mycoplasma, and mycobacteria.⁶²

Socioeconomic status and occupation

The data regarding the association between socioeconomic status and RA are varied. The most recent studies demonstrate an inverse association between socioeconomic status measured by education and occupational class and risk of RA.⁶³ Furthermore, this risk was strongly associated with RF+ RA and not RF- RA in a Finnish cohort.⁶⁴ There was a twofold lower risk of RA in individuals with the longest education compared with those with the lowest level of education. These results concur with those of a previous population-based study in Sweden in which the risk of RA in subjects without university degrees was 40% higher than in those with university degrees. In subjects whose occupation required manual labor, the risk was 20% higher than in nonmanual workers.⁶⁵ Among the occupational exposures related to increased risk of RA are exposure to silica dust and mineral oil.^{65,66} These associations were not seen in a study conducted in the United Kingdom.⁶⁷ Furthermore, low socioeconomic status during childhood, which was based on measures such as level of food insecurity, household income of parents, and young maternal age, was found to be significantly associated with risk of RA.⁶⁸

Urban and industrialized environments

A more general association between RA and urban industrialized environments has been suggested. The influence of urbanization on increased risk of RA is suggested in studies of RA prevalence in urban environments compared with rural environments in both South Africa^{69,70} and Taiwan.⁷¹ However, this association is not seen in all population groups. With the development of reliable methods of studying geographic location, there is evidence that location of residence is associated with differential risk of RA in the US. Women living in the northeastern US had the overall highest risk compared to other regions of the country^{72,73} and exposure to traffic pollution is associated with an increased risk for RA.⁷⁴

HOST FACTORS

Reproductive and endocrine factors

The greater incidence of RA among females, which is most apparent before menopause, suggests an influence of reproductive and hormonal factors. Epidemiologic interest has focused on the influence of pregnancy itself, on risk factors such as breastfeeding in the postpartum period, and on the contribution of endogenous and exogenous hormones.

Nulliparity has been suggested as a risk factor for RA from the results of several case-control studies. However, the association is inconsistent and has not been confirmed in two prospective cohort studies.^{75,76} It is difficult to determine whether any putative association with nulliparity reflects an increased risk of infertility before the development of RA or a protective effect of pregnancy itself. The observations that the frequency of RA is no greater in unmarried than in married women and that family size is similar for patients with RA and for controls suggest that pregnancy does not have a protective influence overall.⁷⁷

Pregnancy may also influence the timing of disease onset. One study showed that the risk of new-onset RA is reduced during pregnancy itself but is increased in the 12 months after delivery.⁷⁸ Another study observed that the risk of RA was related to time since the last birth. The lowest risk of RA was among women who were 1 to 5 years postpartum (relative risk, 0.27; 95% confidence interval, 0.11 to 0.67), with this risk reduction decreasing with increasing time since last birth.⁷⁹

Breastfeeding is also associated with a decreased risk of RA. One prospective study based in the United States observed that breastfeeding for longer than 12 months was associated with decreased risk of RA and that the risk decreases with increasing duration of breastfeeding.⁸⁰ A subsequent case-control study in Sweden confirmed this association.⁸¹ These findings are contrary to those of a previous case-control study, which observed that in the first 12 months after pregnancy, breastfeeding after the first pregnancy increased the risk of RA fivefold.⁸²

The importance of the timing of pregnancy to the onset and severity of RA suggests a contribution from hormonal factors. Early menopause (age 45 years or younger) was associated with an increased risk of subsequent development of RA, even after adjustment for other risk factors such as smoking, level of education, and duration of breastfeeding.⁸³ Androgen deficiency is also thought to play a role in RA risk. The finding that androgen concentrations are lower than expected before the onset of disease in females suggests a possible causal link.⁸⁴ However, another study failed to confirm this association.⁸⁵

Exogenous hormones have also been studied extensively. Overall, the studies of association between oral contraceptive pill use and risk of RA have been conflicting, with two separate analyses reaching opposite conclusions.^{86,87} One study suggested an inverse association for oral contraceptives used in the 1960s when estrogen doses were higher than the current formulations.⁸⁸ There have been fewer studies of the effect of hormone replacement on RA, and a similarly conflicting picture has emerged.

Birth weight

In a case-control study in Sweden, higher weight at birth (more than 4 kg) was found to be associated with as high as a threefold increased risk of RA.⁸⁹ This finding was confirmed by a subsequent study in the United States which showed that babies weighing more than 4.5 kg at birth had a twofold higher risk of developing RA compared with babies who were 3.2 to 3.9 kg at birth.⁹⁰ Although the pathophysiology behind this association is unknown, it is hypothesized that the common pathologic process in the two conditions is hypothalamic-pituitary axis dysfunction, which is associated with both RA and high birth weight.^{91,92}

Preclinical features of rheumatoid arthritis

■ V. MICHAEL HOLERS ■ KEVIN D. DEANE

- Autoimmune diseases including rheumatoid arthritis (RA) typically begin with a prolonged asymptomatic period characterized by the presence of circulating disease-specific autoantibodies.
- RA is characterized by an increase in the number of epitopes recognized by anti-citrullinated protein antibodies as the point of appearance of clinically apparent disease approaches.
- RA is also characterized by an increase in levels of cytokines and chemokines as the onset of clinical disease nears.
- As clinical disease nears, RA-related autoantibodies increase their avidity and the G0 carbohydrate content of immunoglobulin G increases.
- The preclinical state in RA is characterized by the presence of asymptomatic small-airway disease that may play a key role in initiation of the disease.
- Other mucosal tissues, including periodontium, gut, and genitourinary tract, may also be sites of inflammation and/or dysbiosis in preclinical RA.
- Further studies of the natural history of RA are necessary to deepen the understanding of the initiation and propagation of disease.
- Ultimately, well-planned clinical trials in individuals at high risk of future development of RA are necessary to reach the goal of RA prevention.

INTRODUCTION

Definition and primary conceptual underpinnings of preclinical disease in autoimmunity

Traditionally, the field of rheumatology has considered the onset of autoimmune diseases to be the time point when clinically apparent disease occurs. With regard to rheumatoid arthritis (RA), that point would be the first onset of detectable joint discomfort or swelling. However, more recently it has been learned through the efforts of many investigators around the world that there is a prolonged period of highly specific RA-related autoantibody positivity in patients that occurs for several years before the onset of clinically apparent disease (reviewed by Deane and colleagues¹). Therefore new thinking is required about the disease, as well as a new lexicon that incorporates the emerging understanding of the natural history of RA.² One way to envision the current understanding of the natural history of seropositive RA is shown in [Figure 84.1](#).

This autoantibody-positive but asymptomatic period of time is now operationally defined as the *preclinical* period. How asymptomatic an individual is during this period is uncertain, though, because some investigators have included presentations such as “palindromic rheumatism” or “arthralgia” that evolve into classifiable RA as part of the preclinical period.³ Nevertheless, as discussed later, much of the research being performed involves individuals who exhibit a pattern of autoantibodies and biomarkers that indicates that they are at high risk of the *future* development of clinically apparent disease but have not yet transitioned to that period and are indeed asymptomatic. It is understood that a substantial proportion of these individuals will at some point in the future be given a confirmed diagnosis of RA based on either the 1987 American College of Rheumatology (ACR) criteria⁴ and/or the 2010 ACR/European League Against Rheumatism (EULAR) criteria.⁵

Importantly, the finding that preclinical asymptomatic disease evolves into clinically apparent disease only after a prolonged period of highly specific autoantibody positivity is not limited to RA. For example, similar

progression has been observed in the natural history of other autoimmune diseases, including systemic lupus erythematosus,⁶ type 1 diabetes mellitus,⁷ celiac disease,⁸ and Hashimoto thyroiditis.⁹ However, what is remarkable about RA, as compared with diseases such as type 1 diabetes mellitus and thyroiditis—in which the assumption has been that the presence of disease-specific autoantibodies is evidence of ongoing inflammation and organ-specific damage, for instance, in beta cells of the islets—is that the preclinical period is apparently not characterized by detectable arthritis histologically, even in patients who have arthralgia alone without arthritis.¹⁰

Seropositive versus seronegative rheumatoid arthritis

RA is characterized by two major subsets of disease: seropositive and seronegative (reviewed by Fuchs and Sergent¹¹). The discovery of new RA-related autoantibodies such as anti-carbamylated protein antibodies¹² in individuals who lack other RA-related autoantibodies, including rheumatoid factor and anti-cyclic citrullinated peptide antibodies, is decreasing the proportion of seronegative individuals; nevertheless, the seronegative subset is still found. Based on comparative studies of epidemiology and genetic associations, though, it is very likely that the pathogenesis of the two forms of disease is immunologically distinct.^{13,14}

Currently, because of the lack of autoantibody biomarkers, it is not possible to perform effective and informative prospective studies of the natural history of seronegative RA. In addition, many of the inflammation-related biomarkers that one typically sees in seropositive RA are not present at high levels in the preclinical period of seronegative disease.¹⁵ Because of this situation, this chapter primarily focuses on the natural history of seropositive RA.

NATURAL HISTORY OF RHEUMATOID ARTHRITIS

Autoantibodies precede the onset of clinically apparent disease

Importantly, based on a large number of studies performed in the United States, Canada, and Europe using different methodologies and types of retrospective cohorts, it is now known that levels of RA-related autoantibodies are elevated in asymptomatic individuals for up to 5 to 10 years before the development of clinically apparent signs and symptoms of RA.¹⁵⁻²³ As the onset of clinically apparent disease nears, the levels of these autoantibodies rise,¹⁵ and other features described later change. One notable characteristic of this pattern is that the relative duration of RA-related autoantibody positivity in the preclinical period exhibits an age dependence, with older individuals transitioning more slowly to clinically apparent disease than younger individuals.²⁴

Several types of autoantibodies have been detected and characterized in the preclinical period of RA. One type is rheumatoid factor (RF): autoantibodies that react primarily with the Fc domain of immunoglobulin G (IgG; reviewed in Schrohenloher and coworkers²⁵). Importantly, IgM, IgG, and IgA RF isotypes can all be readily measured; this is relevant because each RF test measures a unique population of autoantibodies that share the capacity to react with the Fc domain but differ in their isotypes as well as other physicochemical properties and are thus considered to be the products of related but immunologically distinct processes.²⁶

The second form of RA-related autoantibodies that has been studied is anti-citrullinated protein antibodies (ACPAs; reviewed in Girbal-Neuhauser and colleagues²⁷ and Schellekens and colleagues^{28,29}), for which the primary commercially available test is an enzyme-linked immunosorbent assay

Fig. 84.1 Development of seropositive rheumatoid arthritis (RA) through the initial phase of genetic risk, followed by the asymptomatic development of RA-related autoantibodies. The detail around the transition to early symptoms in the absence of identifiable synovitis is less well understood, but at some point patients develop synovitis and fulfill either 2010 American College of Rheumatology (ACR)/European League Against Rheumatism (EULAR) or 1987 ACR classification criteria. Many epidemiologic factors as noted appear to contribute to the development of the disease, although the phases to which each contributes are uncertain. Anti-CCP, anti-cyclic citrullinated peptide; HPA, hypothalamic-pituitary-adrenal; RF, rheumatoid factor.

BOX 84.1 AUTOANTIBODY CHARACTERISTICS IN THE TRANSITION FROM PRECLINICAL RHEUMATOID ARTHRITIS (RA) TO CLASSIFIED DISEASE

Identified changes in autoantibodies associated with the onset of clinically apparent disease

Increase in levels of anti-cyclic citrullinated peptide (anti-CCP) antibodies
Epitope expansion to additional peptides of anti-citrullinated protein antibodies
Increase in G0 content of immunoglobulin G (IgG) and anti-CCP antibodies
Increase in avidity of anti-CCP antibodies

Potential changes that could increase pathogenicity of RA-related autoantibodies

Ability to fix complement
Ability to engage activating Fc receptors
Development of IgE isotype antibodies

(ELISA) with a cyclic citrullinated peptide (CCP) antigen base of unknown composition. Detection of anti-CCP antibodies by ELISA was originally described as demonstrating a sensitivity of 60% to 70% and a specificity of 98%.^{29,30} More recent studies have modulated the specificity as more diseases have been evaluated and variations of the ACPA evaluation have evolved (reviewed in Demoruelle and Deane³¹). In addition, anti-CCP antibodies have been found in patients with RF-negative RA, and they are associated with the eventual diagnosis of RA in patients who clinically show undifferentiated polyarthritis at presentation.²⁸⁻³⁰

Reactivity to specific citrullinated peptides beyond that identified by standard CCP testing has also been evaluated using both bead-based arrays³² and the ELISA method.³³ Use of a peptide-based Luminex technology to detect elevations in a range of peptide-specific ACPAs has been found to be more sensitive than CCP testing alone for predicting the future development of clinically apparent RA and maintains specificity equivalent to that of anti-CCP testing; this method also detects increases in both the levels and the number of recognized epitopes as the time of clinical presentation approaches.³⁴ ELISA-based methods can also be used to detect elevations of ACPAs in the preclinical period.³³

In seronegative RA, although these individuals did not demonstrate a substantial number of ACPAs, there was evidence of increasing levels of systemic cytokines as the disease onset approached.³⁴ Thus there are some similarities in the biomarker evolution in seronegative RA, although the pattern is much less pronounced.

Modifications and other pathogenic features of autoantibodies evolve as clinical disease onset approaches

In addition to antigen reactivity, isotype, epitope spreading, and levels, there are other key features of autoantibodies that underlie their pathogenicity (Box 84.1). One feature of particular importance to RA is the specific carbohydrate content of IgG, defined as G0, G1, and G2 content. It has been known for several decades that G0 content is increased in individuals with clinically apparent RA, which is important because this type of antibody is considered to be more pathogenic due to its ability to more efficiently interact with Fc receptors and the lectin pathway of

complement.³⁵ Elevations of G0 carbohydrates were found to increase substantially as the time of onset of clinically apparent disease neared.³⁶

Another important characteristic of autoantibodies is the avidity of the mixture for self-antigen. In this regard, using ELISA assays it has been found that ACPAs with intermediate but not high avidity are associated with clinically active disease.³⁷ In addition, when avidity in the preclinical period was assessed, it was found that avidity increased from the preclinical stage to the stage of clinically apparent disease, which suggests that some threshold of avidity needs to be reached for transition from an asymptomatic state to clinically apparent disease.³⁸

What is yet unknown, although under study, is how other features, such as the presence of IgE ACPAs as previously described in patients with established RA³⁹; ACPA complement-activating potential for the classical, alternative, or lectin pathways⁴⁰; and Fc receptor engagement and cellular activation⁴¹ evolve over time in the transition from preclinical to clinical disease.

Other proinflammatory biomarkers increase as clinical disease onset approaches

In addition to changes in levels and other characteristics of RA-related autoantibodies as the time of clinical onset appears, changes in a number of other biomarkers have been shown to occur (Box 84.2). One is the number of cytokines and chemokines that are present in the peripheral blood, which has been shown to increase in an age-dependent manner.¹⁵ Another example is general measures of inflammation such as C-reactive protein. Importantly, there is no canonical pattern of cytokines that evolves in the preclinical period, which suggests that RA can develop through several pathways.^{15,42} Notably, even in first-degree family members of individuals with RA, elevations of certain cytokines are found both in association with elevations of autoantibodies⁴³ and even in the absence of autoantibodies.⁴⁴ This latter finding suggests that there may be genetically based alterations in specific inflammatory pathways that contribute to the risk of RA. Thus these biomarkers serve as measures of risk or impending clinical disease onset but have not yet been highly informative with regard to specific pathogenic processes.

EPIDEMIOLOGY OF PRECLINICAL RHEUMATOID ARTHRITIS

Environmental factors associated with rheumatoid arthritis that may operate in the preclinical period

Cross-sectional and retrospective analyses have identified many potential environmental factors that could play important roles in modifying either susceptibility to RA or disease severity (reviewed in Karlson and Deane⁴⁵). An important exposure that has received substantial recent attention is smoking.^{13,14,46} In addition, environmental lung exposure to silica-containing dust has been linked to the development of disease as well as to the presence of RF in individuals without RA,^{47,48} and a closer residence to a major road as a proxy for exposure to elevated air pollution is associated with an increased risk of RA.⁴⁹

A compelling case for environmental exposures' modifying risk or triggering disease can also be made for infection with certain bacteria and

Fig. 84.2 In this pathogenic scheme, inflammation at one or more mucosal sites in individuals leads to the initial break in tolerance to self-antigens. The common pathogenic mechanism that ties these sites together is systemic spread of the anti-citrullinated protein antibody response and eventual targeting of the joint that is enabled by even transient local inflammation.⁸⁰ RA, rheumatoid arthritis.

viruses. Organisms studied include Epstein-Barr virus,^{50,51} parvovirus B19,⁵² and *Escherichia coli* expressing the dnaJ heat shock protein.⁵³ Substantial evidence also exists in patients with active RA for enhanced reactivity against several bacteria of gut origin, as well as for an increased rate of infection with specific organisms such as *Proteus mirabilis*.⁵⁴ In addition, levels of IgA reactivity against *P. mirabilis*, *E. coli*, *Campylobacter jejuni*, *Salmonella typhimurium*, *Salmonella enteritidis*, *Yersinia enterocolitica*, and *Klebsiella pneumoniae* have all been reported to be increased in individuals with RA compared with control subjects,⁵⁵ which suggests a relationship between RA and changes in gut permeability, specific or general levels of mucosal infection, or alterations of the normally noninflammatory mucosal milieu.

Recent studies have also suggested that the relative levels of specific organisms found in the largely unculturable microbiome is substantially different in patients with early RA at disease onset compared with control

subjects⁵⁶ and that specific changes in the oral microbiome are found.⁵⁷ In addition, individuals at higher risk of the future development of RA exhibit increased levels of antibodies to *Porphyromonas gingivalis* in the serum.⁵⁸ Finally, mycoplasma species have also been proposed to play important roles as environmental triggers of RA.⁵⁹ One way to integrate the findings of pulmonary, oral, and gut microbiome changes into the pathogenesis of RA is illustrated in Figure 84.2.

In addition to risk factors for disease, protective factors reported for RA include oral contraceptive pill use,⁶⁰⁻⁶² successful pregnancy,^{63,64} and dietary components including increased consumption of ω -3 fatty acids in fish and fish oils⁶⁵ and ω -9 fatty acids in olive oil. In addition, low levels of the serum antioxidants α -tocopherol and β -carotene have been proposed to increase disease risk.⁶⁶

Finally, although these associations are present in individuals with clinically active and long-standing RA, the stage at which factors that are associated with increased risk of RA impact the development of autoimmunity and clinically apparent disease is unknown. However, based on available data, it appears that smoking increases risk of the early-stage development of RA-related autoantibodies, whereas oral contraceptive exposure decreases the risk.⁶⁷ Further studies are needed to understand exactly when in the course of RA development these factors may act to trigger or promote disease.

Pulmonary disease in the preclinical period

Substantial prior data suggest that the lung is an important organ that is commonly affected in patients with RA (reviewed in Klareskog and associates¹³ and Demoruelle and Deane³¹). In addition, recent studies have demonstrated that individuals who are at increased risk of the future development of RA by virtue of asymptomatic elevations of ACPAs and/or RFs also exhibit an increased prevalence of airway disease, even in the absence of smoking, which suggests that other potential causes of local inflammation are driving these changes.⁶⁸ Furthermore, ACPA elevations can be found in individuals who have clinically apparent lung disease initially in the absence of inflammatory arthritis and who later progress to clinically apparent articular RA.^{69,70} In total, these findings suggest that the lung could be a site of initial generation of RA-related autoimmunity in a proportion of individuals who develop RA, an assertion supported by studies in patients with established RA which have demonstrated that the airways can be a site of generation of RA-related autoantibodies.⁷¹

THERAPEUTIC APPROACHES TO THE PRECLINICAL PERIOD OF RHEUMATOID ARTHRITIS

The existence of a prolonged stage of preclinical RA (see Fig. 84.1) suggests that if one can identify individuals in this phase and predict the onset of

clinically apparent RA with sufficient accuracy, the next logical step is to determine whether one can prevent the onset of disease.⁷² Certainly previous studies have strongly supported the concept that the earlier the treatment, the better the long-term outcome (reviewed in Demoruelle and Deane⁷³). One expectation is that extending treatment into the preclinical period with the goal of prevention will provide even more benefit.

Prediction of the timing of onset of clinically apparent disease

The major limitation to the development of therapeutic strategies in the preclinical period is the relative lack of understanding of the timing of the onset of clinically apparent disease in individuals positive for high-risk RA-related autoantibodies. Several approaches are being undertaken to identify predictive patterns, and these use two parallel methods. The first is to assess the extent of expansion of epitopes recognized by ACPAs, which is also reflected in the levels of anti-CCP antibodies.³⁴ The other is to evaluate the number and levels of increases in peripheral cytokines and chemokines in the sera of individuals who also exhibit high-risk RA-related autoantibodies¹⁵ (Fig. 84.3). Finally, other combinations of biomarkers are envisioned as being potentially informative in this manner.¹

Risk factor modification

Eliminating in the preclinical phase of RA development factors that may trigger or propagate RA-related autoimmunity may be an effective approach to prevent or modulate clinically apparent disease. In particular, given the importance of the association between smoking and the risk of the development of seropositive RA in individuals with the proper HLA-DRB1 genetic background,^{13,14} it is logical to ask what would be the population-based effect of an intervention to decrease smoking. That question has been addressed by a modeling study conducted in the Swedish population, which estimated that smoking potentially was responsible for up to 35% of cases of ACPA-positive RA and up to 55% of cases of ACPA-positive RA in

individuals with two copies of HLA-DRB1 alleles containing the shared epitope.⁷⁴ Whether smoking provides a similar effect in other populations is uncertain.⁷⁵ In addition, it is not certain what would be the effects of smoking cessation in those who have already developed RA-related autoantibodies and other biomarkers, especially if smoking acts to trigger initial autoimmunity but other factors lead to propagation of RA to clinically apparent disease. Notably, however, in retrospective studies approximately 20 years are required after smoking cessation to diminish the elevated risk of RA development.⁷⁶ Certainly further work is necessary to identify risk factors for RA that impact autoimmunity in the preclinical period of disease development so that mitigation of these factors, including smoking, can be evaluated as prevention strategies for RA.

Approved drug therapies as potential prevention approaches

Recent clinical trials in patients with classifiable RA have focused increasingly on treating patients at earlier and earlier time points following the onset of clinically apparent disease, with almost universally improved long-term clinical outcomes. Thus it is not unreasonable to expect that the use of therapeutics in this period would at a minimum improve long-term outcomes beyond traditional approaches, even if the treatment did not prevent the onset of clinically apparent disease.

In this light, potential approaches to the prevention of clinical onset of signs and symptoms of RA start with the use of traditional small-molecule drugs such as methotrexate or hydroxychloroquine. Beyond this, the use of biologic therapies, especially ones that are predicted to affect ACPA antigen-specific tolerance or responses, are also candidates for consideration.

Additionally, other pharmacologic agents may impact autoimmunity and therefore may be considered in preventive approaches for RA. Candidates include the statins, the use of which in two population-based studies suggested a modest decrease in risk of RA.^{77,78}

Antigen-specific tolerance approaches

Murine studies have been conducted in which the administration of citrullinated filaggrin peptide using a tolerizing approach was successful in diminishing the subsequent development of arthritis and ACPA epitope spreading.⁷⁹ Given these results, if one were to understand what antigens are driving evolution of disease, the development of tolerizing regimens is possible. In this area of human investigation, therefore, research efforts are being focused on determining the “original sin,” that is, the antigen(s) to which tolerance is initially broken, as well as defining the range of ACPA epitopes that are recognized in the preclinical period.

Clinical trial endpoints

With regard to potential trial endpoints, ultimately prevention of the onset of clinically apparent inflammatory arthritis is the goal. However, short of that, other potential endpoints that may be realized in a time frame more applicable to a clinical trial (e.g., 2 to 3 years) include either biomarker-related endpoints such as alterations and improvements in the rate or level of ACPA epitope spreading, or changes in the levels of biomarkers such as cytokines, chemokines, or C-reactive protein.

Treatment of the underlying causal mechanisms of disease

Finally, it is important to include the possibility of using radically different approaches that are directed at the causal mechanisms of disease. Examples of such approaches are treatment of periodontitis, modulation of pulmonary inflammation, and treatment focused on repairing a causal dysbiosis.

CONCLUSION

In summary, RA appears to develop in a series of stages, with a preclinical period present for a substantial time before the onset of clinically apparent inflammatory arthritis. The preclinical stage of RA is characterized by the evolution of multiple autoimmune and inflammatory processes that are measured by a number of specific biomarkers. These biomarkers can also be used to predict both the likelihood and timing of future inflammatory arthritis, although additional studies to refine existing prediction models are needed. Multiple genetic, environmental, and lifestyle factors may play a role in the initiation and propagation of RA-related autoimmunity. Importantly, established and emerging data have led to the concept that RA may

Fig. 84.3 This model was developed as a two-step approach to predict the timing of onset of future rheumatoid arthritis (RA), using blood samples obtained before a diagnosis of RA from members of the United States armed forces. The first step was to select individuals whose blood samples were positive for RA-related autoantibodies highly predictive (>96% specific) for future RA (antibodies to citrullinated peptide antigens and/or two or more rheumatoid factor isotypes). The second step was to test for 48 cytokines and chemokines, with a cutoff for each marker established in healthy controls. An increase cytokine/chemokine count is predictive of a shorter time to diagnosis of RA in an age-dependent fashion. For example, in an individual who was 25 years old at the time of testing, positive results for 30 cytokines/chemokines indicates <1 year until diagnosis of RA; however, in a 55-year-old, that same cytokine/chemokine count indicates ~3 years until diagnosis. In a real-time fashion, this model can be used to predict both the likelihood and timing of future RA in a currently asymptomatic individual.

be a preventable disease. To reach this goal, further natural history studies of RA development are needed to understand key mechanistic aspects of the development of disease. Furthermore, methods to identify individuals in the general population who are at high risk of RA need to be established. Ultimately, all of the aforementioned factors need to be distilled into

well-planned clinical trials in individuals who are at high risk of future RA to prevent clinically apparent disease, with such trials using either established pharmacologic agents or other interventions that are firmly rooted in a mechanistic understanding of RA development and that achieve a balance between risk and benefit.

Clinical features of rheumatoid arthritis

■ RICHARD D. BRASINGTON, JR.

- Morning stiffness and swelling in the wrists and proximal interphalangeal and metacarpophalangeal joints are the typical features of rheumatoid arthritis (RA).
- Early diagnosis of RA is critical, but many cases of “early arthritis” are not RA.
- The 2010 American College of Rheumatology/European League Against Rheumatism classification criteria for RA provide a framework for accurate diagnosis of early RA.
- Anti-citrullinated peptide antibodies occur earlier than rheumatoid factor and are more specific for RA.
- Aggressive early administration of disease-modifying antirheumatic drugs is critical to a good outcome.

INTRODUCTION

Rheumatoid arthritis (RA) is the paradigm of a systemic autoimmune disease characterized by inflammatory polyarthritis. The hallmark of RA is symmetric synovial proliferation and tenderness in multiple joints, particularly the small joints of the hands and feet. Most patients experience joint stiffness or gelling for more than an hour in the morning. The blood of approximately 80% of patients with RA contains rheumatoid factor (RF), an immunoglobulin that binds the Fc region of the IgG molecule, anti-citrullinated peptide antibodies (ACPAs), or both RF and ACPAs. Rheumatoid nodules are seen in about 20% of patients. Thus, an individual with a several-week history of symmetric swelling and tenderness of the small joints of the hands, morning stiffness, and positive RF or ACPA probably has RA.

These clinical features are reflected in the 1987 criteria for the classification of RA developed by the American College of Rheumatology (ACR) (Box 85.1).¹ The criteria were developed for classification of patients with RA for inclusion in research studies, not to make the clinical diagnosis of RA. Though quite specific for the diagnosis, these criteria have significant limitations because our understanding of and approach to RA have changed dramatically since 1987. The 2010 RA classification criteria (discussed in more detail in Chapter 83), developed by a joint working group from the ACR and the European League Against Rheumatism (EULAR), provide a mechanism for the diagnosis of RA before the development of erosive joint disease and persistence of symptoms.² The 2010 criteria apply to patients with definite synovitis for which there is no better explanation than RA. The criteria include the number and distribution of joints with synovitis (but no longer symmetry of involvement), duration of symptoms, erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP), and RF and ACPA. Table 85.1 lists the criteria and explains their application.

Perhaps the most important concept in our contemporary approach to RA is the recognition that prognosis and outcome are improved when disease-modifying antirheumatic drug (DMARD) therapy is started within a few weeks or months of disease onset. We now believe that it is critical to identify RA within a few weeks or months of its onset because immediate institution of DMARD therapy results in better outcomes than when administration of DMARDs is delayed for even several months. It is well established that erosive damage can be seen on radiographs of the hands and feet early in the course of RA. Progression of radiographic damage occurs to a lesser degree in patients receiving early therapy than in those for whom therapy is delayed. Because there appears to be a general correlation between

radiographic damage and disability over time, it is hypothesized that preventing radiographic damage will reduce the extent of disability over the years.³ Patients have a greater likelihood of attaining remission with early treatment. Thus it is axiomatic that the diagnosis of RA be made as soon as possible so that DMARD treatment can be started without delay.

CLINICAL EVALUATION

History

The patient's history is typically strongly suggestive of the development of inflammatory arthritis. Commonly, patients will have polyarthritis of the small joints of the hands, but monoarticular involvement can occur initially. The development of joint symptoms may occur almost overnight, or they may evolve slowly over a period of several months. RF and ACPAs have been found in up to half of patients with RA as long as 5 years before the development of clinical disease, thus suggesting the insidious development of disease over time.⁴ Stiffness or gelling in the joints is present on arising and often takes several hours to abate. An inability to “wring out a washcloth” is common, as is the need to hold a coffee cup with both hands. Patients will typically report soft tissue swelling over the knuckles and describe markedly reduced grip strength. Discomfort in the feet is generally most prominent in the metatarsal area; patients may complain of the sensation of having a “stone in my shoe.” Profound fatigue often accompanies the joint complaints, and anorexia and mild weight loss may occur. Typically, patients with RA do not have rash, fever, headache, visual disturbance, or pleuropericardial symptoms at initial evaluation.

Pain in the joints is universal in patients with RA. The pattern of joint involvement in RA is quite typical in most cases. Affected joints include the proximal interphalangeal (PIP), metacarpophalangeal (MCP), wrist, elbow, shoulder, hip, knee, ankle, and metatarsophalangeal (MTP) joints. However, the quality of the pain may vary depending on the type of joint involvement. For example, the pain associated with chronic inflammatory synovial proliferation may be experienced as a dull ache with little fluctuation in intensity. By contrast, the mechanical pain associated with bone and cartilage damage in the knee or hip, in the absence of inflammation, may be more sharp and acute and be associated with activity and relieved with rest.

Patients with musculoskeletal distress commonly complain of joint “swelling,” even in the absence of detectable abnormality on physical examination. However, patients with RA will probably notice swelling in their hands, particularly the MCP joints. Rings may need to be resized or cut off the swollen finger. “Trigger finger” secondary to flexor tenosynovitis may occur.

Examination and clinical features of specific joints

The key to recognition of the physical findings in RA is the ability to recognize the manifestations of synovial proliferation. Unlike normal synovial lining, which is only one or two cell layers thick, in RA the synovium proliferates out of control. As it grows thicker and covers a greater surface area, the rheumatoid *pannus* (Latin for “cloth”) becomes palpable between the patient's skin and the underlying bone and cartilage. This proliferating synovium has a “doughy” or “squishy” feel on palpation, quite distinct from bony enlargement or synovial fluid. This finding is often referred to as “synovitis”; however, the classic inflammatory signs of heat and redness are usually absent, and external examination cannot determine the functional characteristics of the enlarged synovial tissue. Some prefer to use the term *synovial thickening* to describe palpable synovial proliferation. Because *synovitis* is the most commonly used term, palpable synovial tissue will

BOX 85.1 1987 CLASSIFICATION CRITERIA FOR RHEUMATOID ARTHRITIS

The clinical criteria must have been observed by a physician and have been present for at least 6 weeks. At least four of the seven criteria are required for the diagnosis of rheumatoid arthritis (RA). Individuals can be classified as having or not having RA (no RA). New criteria were developed in 2010.

- Morning stiffness lasting at least 1 hour
- Swelling in three or more joints
- Swelling in hand joints
- Symmetric joint swelling
- Erosions on radiographs of the hands
- Rheumatoid nodules
- Positive rheumatoid factor

TABLE 85.1

2010 ACR/EULAR classification criteria for RA*

	Score
Joint involvement	
1 large joint†	0
2-10 large joints	1
1-3 small joints‡	2
4-10 small joints	3
>10 joints (at least 1 small joint)	5
Serology	
Negative RF and negative ACPA	0
Low-positive RF or low-positive ACPA	2
High-positive RF or high-positive ACPA	3
Acute-phase reactants	
Normal CRP and normal ESR	0
Abnormal CRP or abnormal ESR	1
Duration of symptoms	
<6 wk	0
≥6 wk	1

*The target population should have at least one joint with definite synovitis that is not better explained by another diagnosis. A score of 6 of 10 or greater is needed for classification of definite RA.

†Large joints: shoulders, elbows, hips, knees, and ankles.

‡Small joints: second to fifth metacarpophalangeal (MCP), proximal interphalangeal (PIP), thumb interphalangeal, and wrists.

ACPA, anti-citrullinated peptide antibody; ACR, American College of Rheumatology; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; EULAR, European League Against Rheumatism; RA, rheumatoid arthritis; RF, rheumatoid factor.

Adapted from Aletaha D, Neogi T, Silman AJ, et al. 2010 Rheumatoid arthritis classification criteria. *Arthritis Rheum* 2010;62:2569-81.

subsequently be referred to as synovitis in recognition of the fact that acute inflammation is not necessarily present.

Rheumatoid nodules are quite specific for RA and occur in about 20% of patients, generally those with more severe disease and high-titer RF. It is uncommon for nodules to be present within the first year. A nodule is a mass of inflammatory tissue with a central focus of necrosis, presumably the consequence of vascular inflammation, surrounded by chronic inflammatory cells. Nodules occur over extensor surfaces and joints, at sites of chronic mechanical irritation (elbow, toe, and heel), and in subcutaneous tissue of the fingers. Nodule formation sometimes progresses during methotrexate treatment. Rheumatoid nodules may be confused with gouty tophi, so aspiration for crystals or biopsy is sometimes necessary.

In the hands the MCP and PIP joints are almost always involved (Fig. 85.1), and typically the index and long fingers are more involved than the others. A “four-point” technique in which the examiner uses both index fingers and thumbs is preferred for palpating the small joints of the hands (Fig. 85.2). With the patient’s hand in pronation, the examiner palpates the dorsal and volar aspect of the MCP and PIP joints (Fig. 85.3). Particular attention should be paid to the second MCP joint because synovitis may be especially prominent there. The joint line between the distal metacarpal and proximal phalanx, which is easy to palpate in a normal joint, becomes effaced by the synovitis. The “valleys” between the MCP joints are filled in by synovitis. PIP joint synovitis is more easily recognized by lateral

Fig. 85.1 The hand in early rheumatoid arthritis (RA). The right hand shows swelling of the metacarpophalangeal and proximal interphalangeal (PIP) joints. Swelling of the PIP joints is typical of RA and associated with morning stiffness, difficulty making a fist, reduced grip strength, and tenderness of the affected joints. The left hand showed similar changes. (Reproduced with permission from Dieppe P, Bacon PA, Bamji AN, Watt I. *Slide atlas of clinical rheumatology: the clinical evaluation of rheumatic diseases*. London: Gower Medical; 1982.)

Fig. 85.2 “Four-point” technique for palpating the small joints of the hands. (From Lawry G. *The general musculoskeletal examination*. Iowa City, Iowa: University of Iowa Press; 2002.)

palpation of the joint. In RA, involvement is clearly localized to the PIP joint, unlike the dactylitis (“sausage” digit) of spondyloarthritis. The distal interphalangeal (DIP) joints are rarely involved in RA, perhaps because they have less synovium than the MCP and PIP joints. Rheumatoid nodules may occur on the extensor aspect of the fingers.

Flexor tenosynovitis is common and may lead to “trigger finger.” The flexor tendons for the fingers pass through the A1 pulley near the palmar surface of the MCP joint. Thickening or nodularity may prevent the flexor tendon from sliding smoothly through the pulley and result in a snapping sensation with flexion and extension or result in just flexion, as though pulling the trigger of a gun. Frequently, a palpable nodularity of the tendon can be felt by palpating this area with the index finger as the patient flexes and extends the finger.

Signs of late disease with irreversible damage include “swan neck” and “boutonnière” deformities and subluxation of the MCP joints with “ulnar drift” (Fig. 85.4), often accompanied by atrophy of the intrinsic muscles of the hand. The boutonnière deformity entails flexion of the PIP joint and extension of the DIP joint (see Fig. 85.4). As the central extensor tendon is damaged by tenosynovitis, the PIP joint ruptures through it dorsally, thereby

resulting in lateral and volar displacement of the lateral bands of the tendon. Paradoxically, the lateral bands of the central extensor tendons now function as flexors of the PIP joint, and with tendon shortening, hyperextension of the DIP joint develops. By contrast, the swan neck deformity is basically the opposite of the boutonnière deformity, with hyperextension of the PIP joint

Fig. 85.3 Palpation of the dorsal and volar aspects of the metacarpophalangeal and proximal interphalangeal joints to detect synovial proliferation. (From Lawry G. *The general musculoskeletal examination*. Iowa City, Iowa: University of Iowa Press; 2002.)

and flexion of the DIP joint (see Fig. 85.4). The lateral bands of the central extensor tendon sublux dorsally as the PIP joint herniates in a volar direction. Alternatively, the DIP joint can rupture dorsally through the central extensor tendon (like the PIP joint in the boutonnière deformity). In either case, progressive shortening of the tendon maintains DIP flexion and PIP extension. Early in the course, both the boutonnière and swan neck deformities may be reducible. However, as the disease progresses and the tendons shorten, fixed joint contractures develop.

The thumb can be affected by several deformities. Arguably, the most common has been described as the flail interphalangeal (IP) joint (Fig. 85.5), in which case the patient loses the ability to flex that joint. This results in significant functional impairment because of loss of pinch strength, with the patient pinching the index finger against the proximal phalanx. Surgical fixation of the IP joint in flexion may be required to maintain function. A boutonnière deformity of the thumb develops secondary to MCP synovitis and results in MCP joint flexion and IP joint hyperextension. (Imagine the boutonnière deformity described earlier moved back one joint proximally.) The equivalent swan neck deformity of the thumb develops with dislocation of the first carpometacarpal joint, MCP hyperextension, and IP flexion.

At the wrist, synovial proliferation occurs around the ulnar styloid (see Fig. 85.5), and as the disease progresses, laxity of the radioulnar ligament gives rise to the “piano key” sign as the ulnar styloid moves up and down in response to dorsal pressure from the examiner’s thumb. Carpal tunnel syndrome from compression of the median nerve is quite common and often responds to treatment of the disease. Subluxation of the wrist can result in severe disease (Fig. 85.6). Tenosynovitis of the extensor carpi ulnaris and extensor digitorum communis sheaths in the dorsal aspect of the wrist produces a characteristic pattern that is virtually unique to RA (Fig. 85.7); the tubular swelling of the common extensor tendon sheath ends abruptly just distal to the wrist joint. This often obscures swelling on the dorsum of the wrist (radiocarpal) joint itself. Damage from chronic tenosynovial inflammation and friction from the extensor tendons of the third, fourth,

Fig. 85.4 The boutonnière deformity—flexion of the proximal interphalangeal (PIP) joint and hyperextension of the distal interphalangeal (DIP) joint—results from relaxation of the central slip with “buttonholing” of the PIP joint between the lateral bands. The swan neck deformity—flexion of the metacarpophalangeal (MCP) joint, hyperextension of the PIP joint, and flexion of the DIP joint—may be mobile, snapping, or fixed. Its pathogenesis may be related primarily to PIP or MCP involvement. Combinations of MCP and PIP involvement are less frequent. (Adapted with permission from Hastings DE, Welsh RP. *Surgical reconstruction of the rheumatoid hand*. Toronto: Orthopaedic Medical Management Corporation; 1979.)

Fig. 85.5 Hyperextension of the interphalangeal joint of the right hand illustrates a “flail thumb.” Note also subluxation of the right fifth metacarpophalangeal joint, the prominent ulnar styloid, and ulnar drift. (From *Clinical Slide Collection on the Rheumatic Diseases*, American College of Rheumatology.)

Fig. 85.6 Subluxation of the wrist in severe disease associated with extensor tenosynovitis and extensor tendon rupture. (From *Clinical Slide Collection on the Rheumatic Diseases*, American College of Rheumatology.)

Fig. 85.7 Tenosynovial swelling as a result of tenosynovitis—the “tuck” sign. Tenosynovial swelling overlies the metacarpals of the right hand. Bulging becomes accentuated with full extension of all the fingers of the hand. Persistent tenosynovitis over the dorsum of the wrist may lead to extensor tendon erosion and rupture, particularly of the tendons of the fourth and fifth fingers.

and fifth fingers crossing the jagged and eroded ulnar styloid can lead to tendon rupture with an inability to actively extend those fingers (see Fig. 85.7).

Three characteristic findings occur at the elbow. Synovitis may be palpated between the lateral epicondyle and the olecranon prominence. The radiohumeral joint is just distal to the lateral epicondyle. Swelling of the olecranon bursa often occurs in more severe disease and tends to be bilateral. In fact, bilateral olecranon bursal swelling occurs only in RA, gout, and pseudogout. Finally, the olecranon and extensor surface of the proximal end of the ulna are very common sites for rheumatoid nodules.

Shoulder involvement typically produces significant limitation of motion in all planes. Visible effusion of the glenohumeral joint is unusual but can produce a “shoulder pad” sign. On examination the patient will elevate the scapula to improve range of motion for abduction and elevation. Shoulder pain is often referred to the proximal deltoid region. Evidence of impingement of the supraspinatus and biceps tendons is frequently present. Because of ongoing synovitis, rupture (either partial or complete) of the rotator cuff group of muscles may occur. Tenderness and swelling may also be seen at the sternoclavicular joint.

Spine involvement in RA is limited mostly to the cervical spine, particularly the upper portion. On examination one notices decreased range of motion in all planes. The most critical involvement occurs at the atlantoaxial joint, where the ring of C1 pivots on the odontoid peg of C2 (Fig. 85.8). The transverse ligament of the axis courses around the posterior portion of the odontoid, which prevents subluxation of C1 on C2. Tenosynovitis here can decrease the space available for the upper cervical cord as it passes through the bony spinal canal posterior to the odontoid. This can also lead to laxity of the transverse ligament or erosion of the odontoid, in which case the ring of C1 can move forward on neck flexion (atlantoaxial subluxation) and reduce the diameter of the spinal canal and compress the upper cervical cord (Fig. 85.9). Cranial settling describes caudal migration of the cranium on the spinal column, which results in movement of the odontoid into the foramen magnum, where it compresses vital structures (Fig. 85.10). Subaxial subluxation represents unstable movement of one vertebral body on another below C1-C2. Vertebral artery compromise can also occur as a result of these structural defects.

Significant cervical spine involvement can have protean clinical manifestations, including headache, neck pain, a sensation that the head might fall off, paresthesias, weakness, transient ischemic attacks, and bowel and bladder sphincter impairment. The development of any of these symptoms in a patient with severe RA calls for immediate neurologic examination. Magnetic resonance imaging provides the best information on anatomic derangements in the area.

The hip is frequently affected in RA, and progressive disease can lead to severe secondary osteoarthritis requiring total joint replacement. Pain from the hip joint itself is experienced in the groin and medial aspect of the thigh, sometimes with radiation to the buttock. Pain over the greater trochanter, which most patients refer to as the “hip,” is more likely due to bursitis. The Patrick test (also known by the acronym FABER for flexion, abduction, external rotation) puts the hip through passive motion in all major planes and produces groin pain in the presence of true hip disorders. In later

Fig. 85.8 Relationship between the peg of the odontoid and the arch of C1. (From *Clinical Slide Collection on the Rheumatic Diseases*, American College of Rheumatology.)

Fig. 85.9 This radiograph of a rheumatoid cervical spine in flexion demonstrates atlantoaxial subluxation as the arch of C1 slides forward (arrows). (From *Clinical Slide Collection on the Rheumatic Diseases*, American College of Rheumatology.)

Fig. 85.10 Cranial settling occurs when the cranium migrates caudally onto the odontoid, which impinges on the brain stem above the foramen magnum. The odontoid should not extend much above a line drawn between the white and black arrows. (From *Clinical Slide Collection on the Rheumatic Diseases*, American College of Rheumatology.)

disease it is essential to distinguish symptoms of ongoing synovitis from mechanical pain related to joint damage. Sudden development of hip pain suggests avascular necrosis or fracture in patients taking corticosteroids long-term.

Rheumatoid involvement of the knee joints is easy to detect by physical examination and is often a good indicator of disease activity. Anterior swelling is detectable by the “bulge” sign, in which the examiner strokes the medial part of the knee to move the synovial fluid cephalad and then presses on the lateral aspect of the knee to produce a visible fluid wave, or “bulge,” on the medial part of the knee. With a large tense effusion it may be impossible to move enough fluid to produce a bulge, in which case ballottement of the patella with the index finger produces downward movement of the patella in the fluid. Distention of the posterior compartment of the knee capsule produces a tense Baker cyst in the popliteal region. Rupture of such a popliteal cyst can produce swelling, heat, and pain in the posterior part of the calf, similar to deep venous thrombosis. A hemorrhagic “crescent” sign below the malleoli (Fig. 85.11) may result. Musculoskeletal ultrasound examination can be useful in detecting a popliteal cyst before rupture. Progressive synovitis can lead to loss of articular cartilage, secondary osteoarthritis, and the need for total knee arthroplasty. Examination of synovial fluid can be very helpful in distinguishing between persistent disease activity and mechanical damage. In chronic disease, quadriceps atrophy and flexion contracture are common.

Fig. 85.11 Acute synovial rupture. An effusion in the right knee developed in a 51-year-old man with rheumatoid arthritis of 3 years' duration after an evening of square dancing. Two days later he noted progressive pain and swelling in his right calf. (a) Six days later, bluish discoloration developed on both sides of his ankle. (b) A few weeks later, after more dancing, he noted posterior thigh pain and swelling that soon became associated with purple discoloration on the posterior aspect of his right thigh.

The ankle is another large weight-bearing joint in which active RA can be directly visualized. The capsule of the tibiotalar joint distends anteriorly and effaces the normal contour of the tibialis anterior tendon. The joint line itself can be palpated between that tendon and the medial malleolus, where synovial proliferation can be identified. Progressive damage to the tibiotalar, subtalar, and talonavicular joints can result in ankle and midfoot pronation and loss of the transverse arch and produce mechanical symptoms that can be quite challenging to manage. Tendinitis of the posterior tibialis develops posterior and medial to the medial malleolus. In the same area the posterior tibial nerve can be compressed in the tarsal tunnel, thereby leading to paresthesias on the sole of the foot. “Pump bumps” and rheumatoid nodules commonly develop at the site of shoe friction on the posterior aspect of the heel.

The forefoot is an area of major rheumatoid involvement. Early in disease, examination will reveal tenderness on palpation of the individual MTP joint or on squeezing the forefoot. Swelling can be seen in the dorsum of the foot just proximal to the toes. As the disease progresses, the metatarsals sublux on the plantar aspect of the proximal phalanges and displace the soft tissue fat pads that normally underlie the metatarsal heads. Furthermore, the forefoot broadens and the transverse arch of the forefoot disappears, and thus the patient's metatarsal heads are now directly bearing the weight of the entire body. Calluses develop under the metatarsal heads, and in advanced cases of RA, ulcerations occur at this location. Hammertoes (resembling piano key hammers) develop from increased tension on the flexor tendons secondary to subluxation of the MTP joint.

DIAGNOSIS

RA is a clinical diagnosis for which no single physical finding or laboratory test result is pathognomonic. A broad differential diagnosis must be considered in patients with joint pain and swelling (see Table 85.1). As a practical matter, a patient older than 18 years who has symmetric joint pain, swelling in the hands and feet, and morning stiffness is likely to have RA, especially if RF or ACPA is positive. Its early manifestations can be quite similar to several other conditions, which must be excluded, so one must be cautious to avoid overdiagnosis of RA. On the other hand, early diagnosis is critical so that appropriate treatment can be initiated and irreversible damage does not occur. The 2010 RA classification criteria are very helpful in this regard. Some data suggest that definitive treatment should be started within 3 months of the onset of disease. Therein lies the advantage of the 2010 ACR/EULAR classification criteria for contemporary clinicians: they provide diagnostic support for recognition of early RA, which allows physicians to make a definitive diagnosis without delay and thus to make a decision to administer DMARD therapy timely and before joint destruction occurs.

The ACR/EULAR criteria provide a useful starting point for one to become familiar with the key clinical features of RA (see Chapter 83). The ability to recognize early synovitis in the joints of the hands and feet is critical (see Fig. 85.1). Radiographs of the hands and feet are sometimes diagnostic at initial evaluation, and musculoskeletal ultrasound and magnetic resonance imaging can detect early evidence of synovitis and erosions not seen on radiographs (see Chapter 88), although the aim today is to prevent joint damage from occurring. RF and ACPA tests are readily available and positive in about 80% of patients with RA. However, RF may be negative early in RA, and positive RF may be seen with many other conditions, especially hepatitis C infection.

Differential diagnosis

A number of disorders can closely resemble RA and must be considered and excluded when a diagnosis of RA is being made (see Table 85.1).

NATURAL HISTORY

Disease onset

The clinical course of RA follows an onset of disease that may be abrupt and acute, gradual and insidious, or subacute between these extremes. A gradual onset is most common (at least 50% of cases), whereas a sudden onset is much less common (10% to 25%). RA begins predominantly as an articular disease, and one or many joints may be affected. It may also start as an extraarticular or nonarticular manifestation, such as local bursitis, tenosynovitis, or carpal tunnel syndrome, or as a systemic manifestation with diffuse polyarthralgia or polymyalgia. Although the onset of RA is predominantly articular, it is frequently associated with a variety of extraarticular features, including generalized weakness, anorexia, weight loss, or fever. In some cases, fatigue alone or diffuse nonspecific aching with other extraarticular features such as pulmonary disease may herald—by weeks or months—the onset of polyarthritis.

Patterns of onset

Gradual onset

The most common early finding is a gradual or insidious onset in which small peripheral joints such as the wrist, MCP, PIP, ankle, or MTP joints are affected. It is defined as one that the patient can date only to the nearest month. It is usually symmetric, with considerable morning stiffness, difficulty making a fist, and poor grip strength. The morning stiffness may last minutes to hours.

Slow, monoarticular onset

Less common is a slow monoarticular process affecting larger joints such as shoulders or knees. The symptoms may remain confined to one or two joints but frequently spread over the ensuing days and weeks additively to affect the wrists, fingers, ankles, or feet in widespread fashion.

Abrupt, acute polyarthritis

Less frequently, RA is manifested as an abrupt acute polyarthritis of the shoulders, elbows, wrists, fingers, hips, knees, ankles, and feet, with intense joint pain, diffuse swelling, and limitation leading to incapacitation. A sudden onset is defined as one for which the patient can give a specific date.

This type of onset may affect patients at any age but has particular significance in the elderly.

Acute monoarthritis

Acute monoarthritis of the knee, shoulder, or hip can present a picture suggesting a septic, pseudogout, or gouty process, although this finding is rare. Joint pain more severe than that found in RA is characteristic of pseudogout or gout, which may resemble or even complicate RA. The results of synovial fluid analysis should settle any diagnostic confusion in such cases. An acute monoarticular manifestation may proceed to more widespread involvement with any of the preceding patterns.

Tenosynovitis or bursitis may also be associated with monoarthritis or polyarthritis and subcutaneous nodules over extensor surfaces such as the elbow, sacrum, or Achilles tendon.

Local extraarticular features

As noted, bursitis and tenosynovitis may be associated with RA. Sometimes, however, the earliest manifestation of RA may be median nerve compression (carpal tunnel syndrome) secondary to volar wrist tenosynovitis. Similarly, other local extraarticular features may be the initial feature.

Systemic extraarticular features

Elderly patients, in particular, may have polyarthralgia and polymyalgia affecting the neck and shoulders or the hips and knees and profound fatigue. Although these features, especially in association with fever and a high ESR lasting several weeks, suggest a diagnosis of polymyalgia rheumatica, this picture may be a forerunner of full-blown RA.

Patterns of progression

No matter what the type of onset or signs and symptoms, the patient's subsequent progress may follow several different patterns. It may be a course that is brief and self-limited, episodic (palindromic) or prolonged and progressive, or something intermediate. Severity may vary from mild to intense. Attacks may be prolonged and smoldering or prolonged and progressive.

With continuing disease activity, the patient's daily activities and functional capacity are affected to a greater or lesser extent. Although disability is usually proportional to the amount of painful joint involvement, men who do hard physical work sometimes have progressive joint dysfunction and disability without much pain. The physical ability of patients who have this "neuropathic" picture may dwindle insidiously before work becomes impaired or daily activities decline and the seriousness of the situation becomes apparent. This highlights the importance of careful evaluation and reevaluation of the patient's condition. For this reason, good records are essential for documenting the patient's progress and response to treatment.

Clinical course—morbidity and mortality

Studies of the natural history of RA could provide insight into outcome variables and prognosis. Understanding the prognosis helps in better evaluating the psychosocial and compensation implications for estimating work disability in RA. It is worthwhile considering whether the type of disease onset and patterns of features previously outlined can be used to predict the subsequent course of RA.

Acute-onset pattern

In a series of 102 cases of early adult RA, Fleming and associates⁵ reported that 11 patients with a sudden disease onset showed, after 5 years, a better functional outcome than did 69 patients with a slow onset of disease. However, in a later series of 100 patients, Jacoby and coworkers⁶ observed that after an 11-year follow-up, there was no difference in functional class regardless of whether onset of the disease was acute, subacute, or gradual. In the past, patients with an acute onset as a result of a reactive or viral polyarthritis may have been misdiagnosed as having RA. Another explanation for a better outcome in patients with an acute onset is that they are more likely to seek prompt medical attention. The favorable course of mild, transient, or self-limited RA, however, has not attracted much attention because rheumatologists are concerned mostly with progressive RA.

Gradual-onset pattern

In the report by Fleming and associates,⁵ a worse prognosis was found in patients with disease that was gradual in onset and associated with involvement of large joints (e.g., shoulders, elbows, wrists, knees), in addition to involvement of the first and second MTP joints. In the series of Jacoby and coworkers⁶, the type of onset was not predictive of functional status after

11 years; moreover, in a later Finnish study of 235 patients with RA, radiographically evident damage after 7 years was the same whether the onset had been acute, subacute, or gradual.⁷

Assessment of disease activity

A critical component of providing care to patients with RA is accurate assessment of disease activity and the extent to which the patient's daily functioning is impaired. To some degree this is intuitive and readily evident from the history and physical examination at each visit. However, more quantitative outcome measures are available and can be applied at selected outpatient visits.

Recording a tender joint count (TJC) and swollen joint count (SJC) is simple and straightforward. Controversy exists regarding the ideal number of joints to be counted: 28, 44, 66, or more. The 28-joint count (PIP, MCP, wrist, elbow, shoulder, and knee joints) can be accomplished quickly and efficiently in the office setting,⁸ although some argue that the 44-joint count is more representative of the patient's clinical situation. Assuming that the same examiner performs the count on each visit, it is an accurate and reproducible record of the patient's status. Another objective and quantifiable tool is measurement of an acute-phase reactant, either ESR or CRP. The ESR can easily be determined in the outpatient setting by office staff, whereas CRP is a more complex measurement. A more subjective method is use of a 100-mm visual analog scale (VAS) by the patient or health care provider (or both). Patients can indicate a VAS measurement for pain, global assessment of arthritis activity, or general sense of health. The most common VAS performed by physicians is global assessment of arthritis activity.

Two composite scores have been used extensively and validated: the EULAR Disease Activity Score (DAS) and the ACR Core Data Set. Although both are used to measure outcome in clinical trials of medications for the treatment of RA, the DAS28 is readily adaptable to repeated visits in the outpatient setting. The DAS28 is a discrete variable calculated from the TJC and SJC for 28 joints, the ESR or CRP, and the patient's VAS for general health. A rather complicated calculation that includes logarithmic transformation produces a discrete numeric value between 0 and 10.⁹ A DAS is available online⁸ to easily generate this number. Some investigators have proposed making specific treatment decisions at each visit based on escalating medication treatment to achieve a DAS below a certain threshold level indicating "remission." Further details on disease activity and outcome assessment are provided in Chapter 96.

The Health Assessment Questionnaire (HAQ) has become an established outcome measure that is easily self-administered by the patient in a short amount of time.¹⁰ Originally developed at Stanford University, the HAQ has undergone many iterations, each of which has its proponents. In its simplest form, the questionnaire addresses the patient's ability to perform activities of daily living in eight domains (Table 85.2), for example, getting in and out of bed, bending down to pick up clothing from the floor, and so on. The patient indicates the level of difficulty in performing each activity, and each answer receives a certain score based on where it falls on the continuum (0 = "without any difficulty" to 3 = "unable to do"), and the highest value for each of the eight domains is indicated. These eight values are totalled and divided by 8 to yield an HAQ score. As the score increases, so does the level of disability. HAQ scores can be compared from visit to visit, with a change of 0.22 representing a significant difference. Early in the

disease the HAQ score tends to reflect disease activity, whereas later in the disease it tends to indicate level of disability.

Regular application of such outcome measures allows the clinician to make a quantitative determination of how the patient is doing, which can be especially valuable when assessing a patient's response to a change in treatment. In some situations, documentation of response to treatment is required by health insurance providers as a condition for continuing to provide expensive medications such as monoclonal antibodies or recombinant fusion proteins.

PROGNOSIS

It is critically important for the clinician to make the best possible assessment of prognosis for an individual patient with RA. Despite consensus that all patients with RA should receive DMARDs, the choice of medications individually or in combination for a particular patient depends greatly on the clinician's judgment of the severity of the illness and the likelihood that joint destruction will occur. There is evidence from several trials that some patients have a better outcome if a combination regimen is started immediately as opposed to an approach in which individual agents are added sequentially,^{11,12} and there is strong support for trying to achieve "tight control" in the treatment of RA.¹³ A recent study showed no difference in efficacy between stepping up from methotrexate monotherapy to combination DMARDs versus starting with a combination of methotrexate and a tumor necrosis factor (TNF) antagonist,¹⁴ whereas another study suggested that immediate institution of anti-TNF therapy was superior to combination oral DMARDs.¹⁵ Approaches to treatment are in rapid evolution, and it is unlikely that there will be agreement regarding a single best algorithm for choosing therapeutic agents in the foreseeable future. Nonetheless, prediction of prognosis at the time of diagnosis or when assuming care is essential.

The literature on prognostic factors for RA is voluminous, and no clear consensus has been reached regarding which factor or combination of factors is most important. Several factors reported to influence prognosis are discussed below.

A recent study from France attempted to correlate HAQ scores with subsequent radiographic features.¹⁶ The authors found, as did other studies, that the HAQ score at baseline is an excellent predictor of outcome. Furthermore, the HAQ score has also been shown to predict the risk for future loss of productivity in RA patients.¹⁷

Radiographic damage at onset has been shown to be an important predictor of clinical outcome and radiographic progression. Gossec and colleagues¹⁸ found that a Sharp score (van der Heijde modification) of lower than 4 points at baseline was predictive of remission (DAS28 <1.6) 3 and 5 years later. Not surprisingly, radiographic erosions at baseline are predictive of further radiographic damage 2 to 3 years later.

Acute-phase reactants also have predictive value regarding the development of radiographic damage over time. The ESR at the start of the study was the best predictor of radiographic outcome in the first 5 years in a Swedish study,¹⁹ and the prognostic value of ESR has been demonstrated in other studies. Likewise, baseline CRP is predictive of subsequent radiographic damage.²⁰ Finally, serologic markers may predict prognosis. The presence of RF has consistently been associated with radiographic

progression. Data are emerging that the presence of ACPAs is an independent predictor of radiographic damage.²⁰

In summary, the clinician has a number of readily available tools that can be useful in predicting the prognosis of patients with RA several years later: ESR, CRP, RF, ACPA, HAQ, and baseline radiographs of the hands and

feet. Although it is not possible at present to assign the relative importance of these factors in combination because the presence of each of them has negative implications on prognosis, the presence or absence of these factors can help the clinician make a rational assessment when making treatment decisions for individual patients.

Extraarticular features of rheumatoid arthritis and systemic involvement

■ CARL TURESSON ■ ERIC L. MATTESSON

- Rheumatoid arthritis may be associated with inflammation in extraarticular organs.
- Features of systemic involvement in rheumatoid arthritis include constitutional symptoms, distinct organ manifestations, and severe multiorgan disease.
- Systemic features may be associated with a poor prognosis, especially vasculitis and rheumatoid lung disease.

INTRODUCTION

Constitutional features of rheumatoid arthritis (RA), such as fatigue and weight loss, may occur early in the course of the disease and predominate and overshadow the joint manifestations.

At times, inflammation may extend beyond the joints (Table 86.1). Overall, these systemic manifestations occur equally in men and women and may appear at any age.¹

Extraarticular disease manifestations (except for laboratory abnormalities) occur in about 40% of patients at some time during the course of their disease.¹ The incidence of severe extraarticular disease (vasculitis, vasculitis-related neuropathy, pericarditis, pleuritis, glomerulonephritis, scleritis/episcleritis, Felty syndrome) has been estimated to be 1 per 100 person-years in well-defined RA populations.^{1,2} In recent years a decrease in the incidence of rheumatoid vasculitis¹ and perhaps extraarticular manifestations in general has been observed (see Table 86.1).¹

The systemic inflammatory process is a major predictor of mortality in patients with RA. Extraarticular disease confers a mortality risk ratio five times that in patients without these manifestations, even after comorbid conditions such as heart and lung disease, malignancy, and dementia are accounted for.¹ Some extraarticular disease manifestations, especially vasculitis, pericarditis, pleuritis, amyloidosis, and Felty syndrome, are associated with a diminished life span in comparison to patients without extraarticular disease^{1,3} (Fig. 86.1). The mortality associated with extraarticular disease appears to have diminished somewhat in recent years.¹ Smoking,⁴ the presence of rheumatoid factor and circulating antibodies against citrullinated proteins, and RA-associated HLA-DRB1*04 genes^{5,6} predict extraarticular disease. Other genetic markers, such as HLA-C*03 and genes regulating killer immunoglobulin-like receptor expression on T-cell subsets, may have a particular impact on the risk for vasculitis.^{7,8} Probably because of interactions between these and other risk factors, extraarticular manifestations tend to cluster in individual patients.⁹

The nature of the specific organ involved and the severity of the involvement guide treatment of the extraarticular manifestations of RA. Frequently, therapeutic strategies designed to control joint involvement, including disease-modifying antirheumatic drugs (DMARDs) and glucocorticoids, are effective in treating systemic disease. Although glucocorticosteroids are the mainstay of treatment of systemic disease, cytotoxic agents such as cyclophosphamide are sometimes needed for severe disease, including organ-threatening eye disease and systemic vasculitis.¹⁰ Anti-tumor necrosis factor (TNF) antagonists, B cell-depleting therapies, and other specific immunomodulating agents may be particularly useful in managing these manifestations,¹¹ although extraarticular manifestations sometimes also develop in patients treated with TNF blockers and other biologics.

SKIN DISEASE

Subcutaneous nodules develop mainly in RA patients who are rheumatoid factor positive and rarely in seronegative patients. Patients with rheumatoid nodules early in the course of RA are at an increased risk for the development of severe extraarticular manifestations. Rheumatoid nodulosis (numerous, widespread nodules) occasionally occurs as a separate condition, usually in men, with a low-grade and sometimes barely detectable synovitis.¹²

Nodules develop most commonly on pressure areas, including the elbows, finger joints, ischial and sacral prominences, occipital scalp, and Achilles tendon. Rheumatoid nodules are firm and frequently adherent to the underlying periosteum (Fig. 86.2). Histologic evaluation reveals focal central fibrinoid necrosis with surrounding fibroblasts (Fig. 86.3), which is thought to occur as a result of small-vessel vasculitis. Microchimerism is frequently present in the nodules of patients with RA and may serve as an allogeneic stimulus or target.¹³

Subcutaneous nodules may regress during treatment with disease-modifying drugs, usually as the RA improves. Paradoxically, methotrexate may increase nodules, particularly over finger tendons (Fig. e86.1), despite improvement in the overall disease activity.

Other skin lesions include neutrophilic dermatoses such as Sweet syndrome (Fig. 86.4) and pyoderma gangrenosum. Skin ulcers may be the result of vasculitis or Felty syndrome (see later), venous or arterial insufficiency, and neutrophilic infiltration.

HEMATOLOGIC ABNORMALITIES

The cause of anemia in individuals with RA is multifactorial. Reduced erythropoietin and a blunted response to erythropoietin also contribute to the anemia of RA. Additional factors include increased phagocytosis of red blood cells in the spleen and even by the synovium.

The degree of anemia in RA usually correlates with disease activity, particularly the degree of articular inflammation. It is commonly normochromic and normocytic. The anemia caused by rheumatoid inflammation can improve with therapy that treats the disease successfully. Administration of erythropoietin to RA patients improves red blood cell counts.¹⁴

Thrombocytosis is a frequent finding in active RA. The degree of thrombocytosis may correlate with the number of joints involved with active synovitis and may be associated with extraarticular features. Thrombocytopenia is rare in RA, except when related to drug treatment or Felty syndrome.

Lymphadenopathy is frequent in active RA. Histologic examination usually reveals benign follicular hyperplasia. Patients with RA, however, have a higher risk for malignant non-Hodgkin lymphoma than the general population does.¹⁵ High disease activity¹⁶ and concomitant Sjögren syndrome¹⁷ may confer increased risk for lymphoma.

FELTY SYNDROME

Felty syndrome is defined as RA in combination with splenomegaly and leukopenia. The syndrome characteristically occurs in patients with longstanding, seropositive, nodular, deforming RA. In white patients, the major histocompatibility locus associations with Felty syndrome are the result of

Fig. e86.1 Rheumatoid nodules in a patient with long-standing rheumatoid arthritis treated with low-dose methotrexate weekly.

TABLE 86.1

Extraarticular disease manifestations in a community-based sample of patients with rheumatoid arthritis 1995–2007

Extraarticular manifestation	10-Year cumulative incidence (%)
Pericarditis	2.6
Pleuritis	1.9
Major cutaneous vasculitis	0.6
Vasculitis-related neuropathy	0.2
Felty syndrome	0.5
Scleritis	0
Episcleritis	0.7
Glomerulonephritis	0
Amyloidosis	0
Secondary Sjögren syndrome	9.6
Pulmonary fibrosis	5.0
Bronchiolitis obliterans	0.7
Subcutaneous rheumatoid nodules	31.2

Data from Myasaeova E, Crowson CS, Turesson C, et al. Incidence and mortality of extraarticular rheumatoid arthritis in Olmsted County, Minnesota, 1995–2007: a population-based study. *J Rheumatol* 2011;38:983–9.

SURVIVAL OF PATIENTS WITH EXTRA-ARTICULAR MANIFESTATIONS OF RHEUMATOID ARTHRITIS

Fig. 86.1 Increased mortality in patients with extraarticular manifestations of rheumatoid arthritis. Curves illustrate survival by disease subset.

linkage disequilibrium with HLA-DRB1*0401.¹⁸ Some patients have no active synovitis at the time that Felty syndrome develops. Many of these patients have indolent lower extremity ulcerations (Fig. 86.5), hyperpigmentation, and antinuclear antibodies.

Bacterial infections are common in Felty syndrome and correlate with a polymorphonuclear leukocyte count lower than $100/\text{mm}^3$, and they account for substantial mortality in this condition. Other factors associated with an increased incidence of infections are skin ulcers, the dose of glucocorticosteroid, hypocomplementemia, and high levels of immune complexes. Bone marrow is usually normal or hyperplastic. In some patients, however, bone marrow does not respond appropriately to the degree of leukopenia, perhaps because of inhibitors induced by proinflammatory cytokines that suppress myelopoiesis.¹⁹ Thrombocytopenia also occurs in Felty syndrome.

Treatment strategies for Felty syndrome may include methotrexate,²⁰ parenteral gold²¹ (grade C), glucocorticoids, granulocyte colony-stimulating factor, and splenectomy.

Risk for the development of lymphoproliferative and other malignancies is increased in patients with RA, particularly in those with Felty syndrome.¹⁵

Fig. 86.2 Gross anatomic specimen of a rheumatoid nodule. The yellow tissue is caused by fibrinoid necrosis.

Fig. 86.3 Rheumatoid nodule with granulomatous transformation. Prominent central fibrinoid necrosis is present along with surrounding palisading histiocytes and an outer layer of chronic fibrosing connective tissue with inflammatory cells, including lymphocytes and fibroblasts (hematoxylin-eosin; original magnification $\times 450$).

Fig. 86.4 Neutrophilic dermatosis (Sweet syndrome) in a patient with multiple erythematous plaques and pustules.

Fig. 86.5 Indolent and recurrent lower extremity ulcer in a typical midshaft location in a person with Feltz syndrome.

Fig. 86.6 Large granular lymphocytes.

A variant of Feltz syndrome has been described in which patients have neutropenia and an increase in the number of large granular lymphocytes in blood and bone marrow²² (Fig. 86.6). The large granular lymphocytes in these patients represent *in-vivo* activated cytotoxic T cells, and clonality is present. However, rapidly progressive malignancy with decreased survival is unusual.

HEPATIC ABNORMALITIES

Active RA may be associated with an increase in liver function abnormalities, which may parallel the anemia, thrombocytosis, and increased erythrocyte sedimentation rate. With control of the rheumatoid inflammation, the liver function abnormalities return to normal.

Liver involvement, including hepatomegaly, may be present in up to 65% of patients with Feltz syndrome.²³ Histologic abnormalities may even be present when liver function test results are normal. The liver pathology varies from portal fibrosis and abnormal lobular architecture to nodular regenerative hyperplasia. Portal hypertension, esophageal varices, and variceal bleeding can develop in these patients.

Fig. 86.7 Pleural effusion and rheumatoid nodule in a person with rheumatoid arthritis. Changes associated with diffuse interstitial fibrosis are also present.

PULMONARY INVOLVEMENT

Pulmonary involvement in RA occurs frequently, although it is not always recognized clinically.²⁴ Men are affected more often than women. In autopsy studies, involvement of the pleura is reported in up to 50% of individuals with RA but detected clinically in only about 7% to 10% of such cases.^{1,25} Rheumatoid pleural effusions are usually exudates with mixed cell counts, high lactate dehydrogenase concentrations, and high protein concentrations (>4 g/L). The presence of multinucleated giant cells is highly specific for rheumatoid pleuritis, but such cells are seen in less than 50% of these cases. Glucose concentrations are often lower than 25 mg/dL (1.4 mmol/L).

Parenchymal pulmonary nodules (Fig. 86.7) are generally asymptomatic and found in seropositive RA patients with widespread synovitis and, usually, nodules elsewhere. The pulmonary nodules tend to be peripheral in location and can measure less than 1 cm or up to 6 to 8 cm in diameter. They can cavitate and cause pleural effusions and bronchopleural fistulas. Pathologic examination of the nodules reveals a central necrotic zone surrounded by a cellular area of proliferating fibroblasts. The differential diagnosis of pulmonary rheumatoid nodules includes neoplasms, tuberculosis, and fungal infections. In the case of a solitary rheumatoid nodule in the lung, excisional biopsy may be necessary to confirm the diagnosis. Treatment of the underlying rheumatoid disease frequently results in improvement in the pulmonary nodules.

Pulmonary nodulosis and pneumoconiosis in patients with RA (Caplan syndrome) is characterized by several nodules greater than 1 cm in diameter scattered throughout the peripheral lung field (Fig. e86.2). Caplan syndrome is seen in individuals with extensive exposure to coal dust, although exposure to silica and asbestos may also lead to pulmonary nodulosis in these patients.

In patients with RA, interstitial lung disease (ILD) generally takes the form of nonspecific interstitial pneumonitis or usual interstitial pneumonitis (Fig. 86.8). The lifetime risk for the development of symptomatic ILD in a community-based population of patients with RA was found to be 7.7%, which is nine times higher than the risk for ILD in the general population.²⁵ Patients with RA-associated ILD have a three times higher risk for death than do patients without ILD, with median survival after a diagnosis of ILD being 2.6 years. The most common radiographic finding is bilateral basilar interstitial abnormalities, which are often asymmetric. Initially, these abnormalities may appear as patchy alveolar infiltrates; with progressive disease a more reticulonodular pattern is seen. High-resolution computed tomography (CT) and open lung biopsy are considered the “gold standard” methods for diagnosing ILD. The clinical features and course of pulmonary fibrosis in RA have been reported to be similar to those of idiopathic pulmonary fibrosis, but response to immunosuppression may be better if the

Fig. e86.2 Caplan syndrome.

Fig. 86.8 Usual interstitial pneumonitis in an 83-year-old man with a 23-year history of rheumatoid arthritis.

Fig. 86.9 Diffuse interstitial pneumonitis with sclerosing alveolitis. Lymphocytes are prominent (hematoxylin-eosin stain; original magnification $\times 150$.)

pulmonary fibrosis occurs in the context of RA or other collagen diseases.²⁶

Rheumatoid ILD is seen more frequently in men than in women, particularly in those who have long-standing nodular, seropositive disease and in patients who smoke. The histologic findings and results of bronchoalveolar lavage can be variable and range from lymphocytic alveolitis to neutrophilic inflammation. Features on routine histologic examination of lung biopsy specimens are nonspecific and include an inflammatory infiltrate with lymphocytes, plasma cells, and histiocytes (Fig. 86.9). B cells and CD4⁺ T cells may be more abundant in the lung tissue of patients with RA-associated ILD than in patients with idiopathic ILD (Fig. e86.3).^{27,28} The greater density of T and B cells observed in RA-related ILD has been linked to high levels of circulating anti-cyclic citrullinated peptide antibodies.²⁹ Tumor necrosis factor (TNF) inhibitors may have a negative effect on RA-associated interstitial pneumonitis in some cases,³⁰ possibly because of the direct antifibrotic properties of TNF.³¹ RA-associated interstitial pneumonitis needs to be distinguished from methotrexate-induced toxicity, which usually has a subacute onset with rapidly progressive respiratory symptoms, less radiographic evidence of fibrosis, and a histologic pattern dominated by eosinophilia and type II pneumocyte hyperplasia.

Cryptogenic obstructive pneumonia (COP) in patients with RA generally responds to glucocorticosteroid treatment and often has a good prognosis. Obliterative or constrictive bronchiolitis responds poorly to treatment and has a worse prognosis. Patients have shortness of breath and a nonproductive cough, but unlike COP, there is not usually any fever or other constitutional symptoms.

Fig. 86.10 Laryngeal edema with cricoarytenoid arthritis on direct laryngoscopy. Black arrow, left arytenoid; black arrowhead, right arytenoid; white arrowhead, left vocal cord; white arrowhead, right vocal cord. (Courtesy Dr. Yuki Nanke.)

Obstructive lung disease is more common in patients with RA than in age-matched controls; it occurs in 9.6% of patients with RA and 6.2% of controls.³² High-resolution lung CT reveals that up to 50% of patients with RA have bronchiectasis and bronchiolectasis,³³ possibly because of increased susceptibility to airway infection, obstructive airway disease, and genetic predisposition.

Upper airway obstruction in RA can also be caused by inflammation of the cricoarytenoid joint. Symptoms include sore throat, hoarseness, dysphagia, pain with speech, pain radiating to the ears, foreign body sensation in the throat, and difficulty with inspiration. Laryngoscopy and CT are the most sensitive methods for evaluating cricoarytenoid arthritis (Fig. 86.10).

CARDIAC DISEASE

RA may lead to cardiac and noncardiac vascular disease^{3,34} through mechanisms of chronic inflammation, vasculitis, nodule formation, amyloidosis, serositis, valvulitis, and fibrosis. Though usually asymptomatic, pericarditis is the most common cardiac manifestation of RA and is found on random electrocardiographic evaluation and autopsy studies in 50% of individuals.³⁵ Analysis of pericardial fluid reveals changes similar to those found in rheumatoid pleural effusions. Symptomatic patients with mild disease generally respond to glucocorticosteroids; pericardiocentesis, intrapericardial glucocorticoid administration, and even pericardiectomy may sometimes be required for management³⁶ (Figs. 86.11, 86.12, and e86.4).

Nonspecific myocarditis is usually asymptomatic and rarely affects cardiac size or function. Congestive heart failure may be more frequent than is clinically evident in RA, and left ventricular diastolic function is more often impaired than in those without RA despite normal left ventricular systolic function.³⁷ Valvular lesions, aortic root abnormalities, and coronary arteritis can also occur (Fig. 86.13).

RA itself is an independent risk factor for coronary artery disease,³⁸ and patients with severe extraarticular disease have a particularly increased risk for cardiovascular death.³ It has been suggested that coronary artery disease may be associated with clonal expansion of CD4⁺CD28null T cells,³⁹ which has also been seen in patients with RA, particularly in those with vasculitis. It has been proposed that atherosclerosis should be regarded as an extraarticular feature of RA.³⁸ Biomarkers of inflammation predict cardiovascular events in the general population,⁴⁰ and vascular disease is more likely to develop in patients with RA and a persistently elevated erythrocyte sedimentation rate.³ Successful DMARD therapy with methotrexate⁴¹

Fig. 86.12 Gross anatomic specimen obtained at radical pericardiectomy showing constrictive pericarditis. The fibrotic pericardium is massively thickened, with a diameter of up to 0.5 cm; the outer layer of the pericardium is covered with fat at the top.

Fig. 86.13 Coronary arteritis. Two arteries are seen. A dense inflammatory infiltrate is present in the adventitia, with some intimal luminal narrowing and destruction of the media of one artery (hematoxylin-eosin stain; original magnification ×250).

Fig. 86.14 Episcleritis usually occurs in the setting of active rheumatoid arthritis and is associated with the sudden onset of redness and eye pain.

Fig. 86.15 Scleromalacia in a patient with rheumatoid arthritis.

or TNF blockers⁴² may substantially reduce the risk for cardiovascular comorbidity.

OCULAR INVOLVEMENT

The most common ocular involvement in RA is keratoconjunctivitis sicca, which affects at least 10% of patients. The severity of the symptoms may not correlate with the severity of the arthritis.

Episcleritis usually correlates with the activity of RA (Fig. 86.14). This process, which may be either nodular or diffuse, develops acutely and causes eye redness and pain; only rarely does it cause changes in visual acuity. Scleritis is less common than episcleritis but is correlated with vasculitis, long-standing arthritis, and active joint inflammation. Untreated scleritis may progress to scleromalacia (Fig. 86.15). Episcleritis or scleritis is sometimes seen in patients whose polyarthritis has responded well to treatment.

Other unusual ocular findings in RA include uveitis, episcleral nodulosis, ulcerative keratitis ("corneal melt," which may be central [Fig. e86.5] or peripheral [Fig. 86.16]), and corneal filamentary keratitis (Fig. 86.17). Peripheral ulcerative keratitis develops as an extension of scleral inflammation, is sometimes bilateral, and may occur in the absence of scleritis. These conditions are associated with increased mortality and poor visual outcomes.⁴³ Treatment may include topical or systemic cytotoxic or glucocorticosteroid therapy, anticytokine agents, or both. Lesions resembling vasculitis may be seen in the limbal part of the cornea, and conditions such as scleritis and ulcerative keratitis can herald impending vasculitis.⁴³ The most common fundus lesions are caused by posterior scleritis; exudative retinal detachment and disc and macular edema may also be found in association with RA.

Fig. e86.5 Central keratolysis and corneal perforation. This is an example of how corneal collagen can degrade in the absence of corneal inflammation in patients with rheumatoid arthritis.

Fig. 86.16 Marginal corneal melt (ulcer) with inflammation.

Fig. 86.17 Corneal filamentary keratitis with early corneal stromal activity near the limbus at the 8 o'clock position and 9:30. Filamentary keratitis concentric to the limbus can be a precursor of marginal corneal ulceration in rheumatoid arthritis.

Other uncommon ocular complications of RA include Brown syndrome, which is defined as diplopia on upward and inward gaze and is thought to be the result of inflammation and thickening of the superior tendons and optic neuritis.

NEUROLOGIC IMPAIRMENT

Peripheral entrapment neuropathy, which tends to occur when the nerve is compressed by the inflamed synovium against a fixed structure, and atlantoaxial subluxation may cause neurologic impairment in patients with RA. Atlantoaxial subluxation caused by erosion of the odontoid process or the transverse ligament of C1 may allow the odontoid process to slip posteriorly and cause cervical myelopathy (Fig. 86.18). Basilar invagination with upward impingement of the odontoid process into the foramen magnum can also result in cord compression (Fig. 86.19). The presence of cord compression is indicated by a positive Babinski sign, hyperreflexia, and weakness. Surgical stabilization may be required.

Peripheral neuropathy manifested as diffuse sensorimotor neuropathy or mononeuritis multiplex occurs in a small subset of patients with RA. The underlying mechanism is small-vessel vasculitis with ischemic neuropathy.

Involvement of the central nervous system in RA is rare. A diffuse, granulomatous pachymeningitis with fever and headache occurs rarely (Figs. 86.20 and e86.6), and vasculitis and amyloidosis may occasionally involve the dura or choroid plexus in patients with long-standing RA.

Fig. 86.18 Plain film of the cervical spine showing erosion of the odontoid.

Fig. 86.19 Magnetic resonance image of the cervical spine showing basilar invagination.

MUSCULAR INVOLVEMENT

Muscle weakness in RA is usually due to muscle atrophy secondary to joint inflammation. Nutritional problems, medication, and neurologic dysfunction may contribute. A rare inflammatory myopathy with patchy lymphocytic and plasma cell infiltration in muscle fibers that results in some fiber degeneration has been described. RA may coexist with idiopathic inflammatory myopathy without other signs of systemic disease.

RENAL ABNORMALITIES

Patients with RA are at higher risk for all causes of chronic kidney disease (CKD).⁴⁴ Inflammation and concomitant cardiovascular disease, as well as

Fig. e86.6 Rheumatoid arthritis–associated meningitis (same patient as in Fig. 86.20) with necrotizing granulomatous meningitis. Cultures were negative and the patient improved after immunosuppressive treatment (hematoxylin-eosin stain, original magnification $\times 200$).

Fig. 86.20 Rheumatoid arthritis–associated meningitis in a patient with headache and fever. Magnetic resonance imaging shows abnormal leptomeningeal enhancement, especially of the left parietal and frontal lobes and temporal dura (arrows).

Fig. 86.21 Renal amyloidosis in rheumatoid arthritis (secondary amyloidosis). Diffuse amyloid deposition is present throughout the renal parenchyma, with deposition in blood vessel walls. Amyloid deposits are green (sulfated Alcian blue; original magnification ×400).

medications, play a role in RA-associated CKD. Low-grade membranous nephropathy, glomerulitis, vasculitis, and nephrotic syndrome as a result of secondary reactive amyloidosis have all been described. In patients with RA who undergo kidney biopsy, the most common histopathologic finding is mesangial glomerulonephritis, and amyloidosis is the most common finding in patients with nephrotic syndrome.⁴⁵ Perinuclear antineutrophil cytoplasmic antibody has been found in about 20% of patients with RA and renal diseases of various cause and may be an independent predictor of nephropathy, even in the absence of systemic vasculitis.⁴⁶ Mesangioproliferative glomerulonephritis is considered a sign of systemic organ involvement in patients with RA.

AMYLOIDOSIS

Amyloidosis may rarely complicate long-standing RA. Reports of its occurrence vary widely, but more recent population studies indicate that clinical visceral amyloidosis is detected in 0.7% of patients with RA.¹ In patients with active RA, serum amyloid A protein concentrations are increased as a result of stimulation by increased cytokine production.

Virtually every organ system may be involved in secondary amyloidosis. The diagnosis is confirmed by biopsy of involved tissue (Fig. 86.21). The presence of secondary amyloidosis in patients with RA portends a poor outcome: 4-year survival rates of about 58% are reported.⁴⁷ Cytotoxic drugs may improve the prognosis, but progressive organ failure often occurs despite aggressive treatment.

Fig. 86.22 Artery with intimal proliferation and luminal occlusion (hematoxylin-eosin stain; original magnification ×312).

Fig. 86.23 Nail fold infarcts in a patient with rheumatoid arthritis.

RHEUMATOID VASCULITIS

Small-vessel vasculitis is intimately associated with many of the clinical manifestations seen in RA. Subclinical vasculitis is probably common in patients with seropositive RA, and immune deposits have been demonstrated in clinically uninvolved skin and labial salivary glands.⁴⁸

Systemic endothelial activation has been suggested in patients with severe extraarticular disease, even in the absence of overt signs of vasculitis.⁴⁹ Inflammation of small and medium-sized arteries in the extremities, peripheral nerves, and occasionally other organs may complicate RA. The frequency of HLA-DRB1 alleles and particularly B1*0401 homozygotes is greater in patients with rheumatoid vasculitis than in those with uncomplicated RA.^{5,6}

Study of involved vessels from patients with rheumatoid vasculitis reveals a pathologic picture and distribution similar to that seen in polyarteritis, but renal involvement is rare. Early lesions show fibrinoid necrosis of the vessel wall with an inflammatory cell infiltrate. Chronic changes such as arterial wall fibrosis, occlusion, and recanalization may be seen (Fig. 86.22). The acute arterial lesions are immune complex mediated, as indicated by the involved arteries (Fig. e86.7). Immune deposits are not detected in the more chronic lesions; rather, fibrinogen is found (Fig. e86.8).

Systemic vasculitis is uncommon in RA but often occurs in rheumatoid patients with long-standing disease of more than 10 years' duration. Rheumatoid synovitis may not be active when features of the systemic vasculitis are present. Small-vessel vasculitis commonly involves the skin and causes nail fold infarcts (Fig. 86.23), digital gangrene (Fig. 86.24), and leg ulcers. The rapid, progressive, and widespread appearance of new areas of involvement, including clinical cutaneous vasculitis and multiple neuropathies, is indicative of systemic arterial disease and portends a worse outcome.⁵⁰

Treatment of rheumatoid vasculitis must be individualized. In patients with progressive widespread systemic vasculitis involving peripheral nerves, digits, viscera, or the central nervous system, the inflammation must be treated and the resulting vasculopathy anticipated. High doses of prednisone may be needed initially to control the inflammation. Two controlled trials

Fig. e86.7 Immunoglobulin M in an artery with fibrinoid necrosis (IgM by immunofluorescence; original magnification $\times 312$).

Fig. e86.8 Fibrinogen in an artery with intimal proliferation (fibrinogen by immunofluorescence; original magnification $\times 312$).

Fig. 86.24 Digital tip and proximal infarcts and mononeuritis multiplex with bilateral footdrop in a patient with rheumatoid vasculitis.

have demonstrated that pulsed⁵¹ or continuous⁵² cyclophosphamide leads to greater clinical benefit than more conservative treatment regimens do in patients with systemic vasculitis (grade B). Even though TNF inhibitors may be useful in the management of vasculitis, they have also been associated with cutaneous small-vessel and systemic vasculitis.^{52,53} Anti-B cell therapy is emerging as effective treatment of rheumatoid vasculitis, either as primary therapy or in patients refractory to cyclophosphamide (grade C).⁵⁴ Low-dose aspirin as an antiplatelet agent should also be considered, and prostacyclin infusions may be helpful in patients with threatening peripheral gangrene. Patients with vasculitis and other forms of severe extraarticular involvement are at an increased risk for cardiovascular events and severe infections and should be monitored adequately for such complications. Preventive measures such as statin therapy should be considered in patients with high cardiovascular risk because patients with RA may benefit from both the antiinflammatory and lipid-lowering effects of statins.⁵⁵

Adult-onset Still disease

■ ELENA RIERA ALONSO ■ ALEJANDRO OLIVÉ

- Adult-onset Still disease is an uncommon autoimmune inflammatory disease most often seen in young adults.
- Clinical findings consist of a combination of systemic manifestations (mostly spiking fever, evanescent rash, and lymphadenopathy) and joint symptoms ranging from arthralgia to aggressive arthritis.
- No specific diagnostic test is available; the clinical diagnosis is based on pattern recognition and exclusion of other diseases.
- The outcome is unfavorable in a third of patients, in whom chronic arthritis develops.
- Therapeutic decisions should be based on the extent and severity of organ involvement. Nonsteroidal antiinflammatory drugs, glucocorticoids, methotrexate, and biologic therapies are good options. There is a lack of clinical trials on adult-onset Still disease.

INTRODUCTION

In 1897 George Frederic Still first reported 22 cases of chronic seronegative polyarthritis in children with periods of fever, lymphadenopathy, and splenomegaly, as well as pericardial adhesions¹; this disease is currently known as the systemic subset of juvenile idiopathic arthritis (JIA) and has the accepted eponym of Still disease. The term *adult-onset Still disease* (AOSD), or Still disease in adults, was introduced by Eric Bywaters in 1971, who described 14 cases of an illness starting in adult life that resembled Still disease.² Currently, systemic JIA and AOSD are considered the same entity.

EPIDEMIOLOGY

AOSD is a rare disease, and at this time there is no consensus on its incidence and prevalence in different populations. It occurs worldwide and affects women slightly more than men, as well as younger people, with three quarters of patients reporting onset of the disease between 16 and 35 years of age.³ However, patients older than 70 years have been reported. The annual incidence estimated in retrospective European studies is 0.1 to 0.4 per 100,000 inhabitants.⁴⁻⁶ Additional data on the epidemiology of AOSD are needed.

ETIOPATHOPHYSIOLOGY

The etiology of AOSD is currently unknown. Interplay among several factors contributing to the mechanism of the disease has been speculated. The hypothesis that AOSD may be a reactive syndrome in which various infectious agents may act as disease triggers in a genetically predisposed host has been classically accepted. More recently, it has been suggested that alterations in cytokine production have an important pathophysiologic role in AOSD.

Genetic predisposition

Although HLA antigens have been associated with susceptibility to AOSD (HLA class II types DRB1*15 and DRB1*12 in Korea)⁷ and clinical prognosis (HLA class I types B35 with self-limited disease and DR2 and DR5 with a chronic course in Japan),⁸ other studies have not confirmed these findings.⁹ Therefore, studies conferring genetic associations with the disease and disease patterns are inconclusive.

Infectious component

Some viral syndromes closely resemble the clinical findings in patients with AOSD, and a temporal relationship between disease onset and viral or bacterial syndromes has been described. Many viruses have been reported to interact with the genetic background of the host (parvovirus B19, rubella virus, mumps, echovirus 7, human herpes virus 6, parainfluenza virus, Epstein-Barr virus, cytomegalovirus, coxsackievirus B4, adenovirus), as well as some bacterial infections (*Chlamydia pneumonia*, *Yersinia enterocolitica*, *Brucella abortus*, and *Borrelia burgdorferi*),¹⁰ but no proof of an infectious etiology has yet been established.

Immune dysregulation

Currently, it is thought that the immune response is dysregulated in patients with AOSD. On one hand, innate immunity with macrophage and neutrophil activation possibly under the effects of the proinflammatory interleukin-18 (IL-18) has been implicated.¹¹ On the other hand, adaptive immunity with a predominance of type 1 helper T-cell (Th1) responses as indicated by increased levels of interferon- γ , tumor necrosis factor- α (TNF- α), and IL-2 has been associated with disease activity.¹² Moreover, the role of Th17 responses is emerging in the pathogenesis of AOSD, and levels of Th17-related cytokines, including IL-1 β , IL-6, IL-17, IL-18, IL-21, and IL-23, are elevated.¹³

CLINICAL FEATURES

The typical features of AOSD consists of a triad of symptoms that include high spiking fevers, evanescent rash, and arthritis or arthralgia. Not all three symptoms need be present at disease onset, and atypical findings may occur; therefore, the pleiotropic manifestation often leads to delays in diagnosis and treatment. In general, a shared constellation of clinical features can be found in most cohort studies reported over the past 7 years from various parts of the world (Table 87.1).¹⁴⁻²⁹

Fever

High fever (temperature $>39^{\circ}\text{C}$) was the initial symptom in more than 95% of patients with AOSD in the largest retrospective studies. Actually, fever of unknown origin is one of the most frequent reasons for patients with new-onset AOSD to seek help, and it is the final diagnosis in about 5% of these patients.¹⁵

The classic fever pattern is one to two daily fever spikes exceeding 39°C , most often occurring late during the day (afternoon or evening) and receding spontaneously within hours. However, continuous fever or early morning spikes are seen in up to 20% of cases.³⁰ Symptoms that occasionally precede the fever and should raise suspicion for AOSD include sore throat, seen in up to 80% of patients, as well as constitutional symptoms such as anorexia, myalgia or arthralgia, fatigue, and weight loss.

Arthritis

Musculoskeletal pain is present in virtually all patients with AOSD at onset and often worsens during periods of fever; such pain includes myalgia (13% to 70%), arthralgia (80% to 100%), and arthritis (18% to 100%). Initially, the arthritis may be mild, transient, and oligoarticular. These manifestations may evolve over a period of months into a more severe, destructive symmetric polyarthritis. Joints affected most frequently are the knees, wrists, and ankles, although involvement of the elbow, shoulder, proximal and distal interphalangeal, metacarpophalangeal, metatarsophalangeal,

temporomandibular, and hip joints has been described as well (Table 87.2). Synovial fluid shows mild to moderate inflammation in most patients. The histopathology is nonspecific and includes chronic synovitis with slight cell proliferation in the synovial lining layers, variable degrees of vascular engorgement, and moderate infiltrates with mononuclear cells.^{30,31}

Early radiographic findings are usually nonspecific and consist of periarticular osteopenia and slight joint space narrowing. Carpal involvement with selective carpometacarpal and intercarpal space narrowing and focal erosive alterations leading to bone ankylosis has been suggested to be a differential diagnostic characteristic between AOSD and rheumatoid arthritis (RA)³² (Fig. 87-1). Severe involvement of the hip joint leading to bilateral hip destruction has also been reported (Fig. 87.2).

■ TABLE 87.2

DIP, distal interphalangeal; MCP, metacarpophalangeal; MTP, metatarsophalangeal; NA, not available; PIP, proximal interphalangeal; TMJ, temporomandibular joint.

Myalgia is generalized and more often appears with exacerbations of fever. Inflammatory myopathy is found rarely, although a number of case reports have described an increase in muscle enzymes, but electromyography and muscle biopsy have not generally been suggestive of myositis.

Rash

The typical rash is an evanescent, salmon-pink, macular or maculopapular eruption that tends to occur with the fever (Fig. 87-3). The rash involves predominantly the trunk and extremities, but the palms, soles, and occasionally the face can also be involved. The Koebner phenomenon may be present in 30% to 60% of patients.^{28,33} Skin biopsy specimens are not diagnostic and show slight inflammatory infiltrates of polymorphonuclear and mononuclear cells in the upper dermis.³⁴ Even though the histopathology is nonspecific, skin biopsy can be important in differentiating this disorder from vasculitis, Sweet syndrome, and other conditions. Atypical skin lesions that have been associated with AOSD include urticaria and persistent pruritic papules and plaques, which show a distinctive distribution of dyskeratotic keratinocytes in the cornified layers, as well as in the epidermis.³⁴

Other frequent findings

Sore throat is common at initial evaluation (55% to 90%) and frequently recurs during a disease flare.³⁵ Examination shows severe, nonsuppurative pharyngitis with negative bacterial cultures.

Lymphadenopathy is detected in 33% to 73% of patients, with the cervical chain being most commonly involved. Splenomegaly may also be present (17% to 64%). The precise relationship between lymphadenopathy and other reticuloendothelial system manifestations such as hepatomegaly or splenomegaly is unclear; its combined presence with constitutional symptoms could lead to diagnostic confusion with lymphoma and even lymph node biopsy. Histopathologic evaluation shows a benign reactive hyperplasia with plasma cells and polymorphonuclear cell infiltration.^{30,31}

Liver abnormalities, predominantly hepatomegaly and abnormalities in liver biochemistry, are present in approximately 20% to 90% of patients. Fulminant hepatic failure requiring liver transplantation is extremely rare.

Fig. 87.1 (a and b) Radiographs of the wrists of a patient with adult-onset Still disease showing narrowing of the carpometacarpal and intercarpal spaces and focal erosive alterations that have led to bone ankylosis in the left wrist.

Fig. 87.2 (a to c) Radiographs of the pelvis showing the typical hip involvement leading to joint destruction.

Fig. 87.3 Example of the typical salmon-pink maculopapular rash affecting the extremities (a) and in more detail (b).

Pericarditis, pleural effusions, and transient pulmonary infiltrates have also been observed in patients with AOSD. Affected patients may complain of cough, pleuritic pain, or mild dyspnea. However, severe interstitial lung disease has been described, and some patients progress to acute respiratory distress syndrome.

Infrequent findings

Over the years, less common findings have been described: myocarditis and cardiac tamponade, aseptic meningitis and encephalitis, seizures, cranial neural palsies, uveitis, interstitial nephritis, collapsing glomerulopathy, renal amyloidosis, and macrophage activation syndrome.

Laboratory findings

The characteristic laboratory findings of AOSD are not pathognomonic, but its presence plus the clinical manifestations should help clinicians establish the diagnosis.

The laboratory profile of the disease is a reflection of the systemic inflammation and cytokine cascade present. The erythrocyte sedimentation rate and C-reactive protein are almost invariably elevated.³⁰ These are typically accompanied by leukocytosis (white blood cell count $>10,000/\text{mm}^3$) with a predominance of neutrophils ($>80\%$), normocytic normochromic anemia (typically the anemia of chronic disease), and thrombocytosis (Table 87.3). These hematologic abnormalities may sometimes reach extreme levels and mimic primary hematologic disease. Bone marrow examination has been reported to show hyperplasia of granulocytic precursors in all patients and hypercellularity and hemophagocytosis in some.³⁶

Abnormal liver enzymes (aspartate aminotransferase, alanine aminotransferase, and γ -glutamyltransferase) can be seen in up to 75% of patients,^{30,37} are more frequent in patients with hepatomegaly, and may show a hepatocellular, cholestatic, or mixed pattern. Abnormal liver function is thought to be part of the inflammatory process of the disease itself and tends to normalize with remission of the disease, although concomitant use of potentially hepatotoxic treatments often complicates interpretation.³⁸

Serum ferritin is markedly elevated in as many as 70% of patients.³⁷ The elevations correlate with disease activity and have been suggested to be a serologic marker for monitoring response to treatment.³⁹ Elevated serum ferritin levels, higher than five times the upper limits of normal (40 to 200 ng/mL), may suggest the presence of the disease with 80% sensitivity and 46% specificity; when combined with a decrease in the proportion of glycosylated ferritin ($<20\%$), the specificity rises to 93%.⁴⁰

Absence of antinuclear antibodies and rheumatoid factor is one of the minor Yamaguchi criteria for AOSD.⁴¹ However, a low titer of either occurs in less than 10% of patients without clinical implications and may reflect their presence in the general population. Complement consumption is rare, with C3 levels in general being normal to slightly elevated in the acute

phase. The presence of anti-citrullinated peptide antibodies has been reported in only 1 of 23 patients tested, but there are no data about their role in AOSD.¹⁷

CLASSIFICATION AND DIAGNOSIS

No specific test is available that can be used for the diagnosis of AOSD. Therefore, the diagnosis is based on recognition of the specific disease pattern and exclusion of other causes: infection, malignancy (lymphoma), necrotizing vasculitis, autoinflammatory syndromes, Schnitzler syndrome, and some drug hypersensitivity reactions such as Drug Reaction with Eosinophilia and Systemic Symptoms (DRESS) syndrome.⁴²

Several criteria sets have been proposed for accurate diagnosis of AOSD^{41,42,43} (Table 87.4). The Japanese criteria (Yamaguchi criteria⁴¹) have the highest sensitivity in patients with a definite diagnosis of AOSD.⁴⁴ The Yamaguchi criteria are hampered by a long list of diseases that must be excluded. The Fautrel criteria, which are more specific, require the not readily available measurement of glycosylated ferritin.⁴⁰

MANAGEMENT

First-line treatment: nonsteroidal antiinflammatory drugs and glucocorticoids

AOSD is not a common disease, and therefore no randomized controlled trials have been performed. Treatment is based on information from observational studies. Therapeutic decisions should be based on the extent and severity of organ involvement.

Nonsteroidal antiinflammatory drugs (NSAIDs) are considered the first-line agents for AOSD. Patients with mild disease may respond. Twenty percent to 25% of patients achieved control with this therapy. No randomized trials have compared different NSAIDs. Aspirin (3 to 4 g daily), ibuprofen (800 mg four times daily), and naproxen (500 mg/twice daily) are selections for initial therapy. Of the NSAIDs, indomethacin (100 to 150 mg/day) seems to be the most effective. It is advisable that liver enzymes be monitored at the onset of therapy. Severe hepatitis has been suggested to be related to treatment with NSAIDs.³⁸

Glucocorticoids are usually required to induce remission of symptoms. Patients with severe symptoms should be treated with glucocorticoids from the outset of therapy. The usual prednisone dose is 0.5 to 1 mg/kg/day. Intravenous pulse methylprednisolone (1000 mg/day times three) is reserved for life-threatening disease such severe hepatic involvement, disseminated intravascular coagulation, cardiac tamponade, and macrophage activation syndrome. No consensus has been reached on a therapeutic tapering scheme

once clinical remission is achieved. Slow reduction over a 6- to 12-month period is recommended to maintain response and avoid relapse. Approximately 70% of patients respond to glucocorticoids. Serious side effects are common.^{45,46}

Second-line therapy: immunosuppressants

Methotrexate (MTX; 10 to 20 mg/wk) is used frequently for the treatment of AOSD. It is efficient in controlling AOSD activity and as a glucocorticoid-sparing agent. It is not clear whether MTX can prevent or limit joint damage in the erosive form of AOSD.

Cyclosporine and tacrolimus are reserved for the treatment of macrophage activation syndrome.^{45,46}

Third-line therapy: biologic agents

Biologic agents have been used for the treatment of AOSD, namely, TNF inhibitors, anakinra, tocilizumab, rituximab, and abatacept.

Tumor necrosis factor inhibitors

TNF blockers have been tested in patients with resistant AOSD. The experience is limited to case reports and small case series. The regimen of administration is the same as for RA. Promising results were reported with infliximab and etanercept, but treatment failures and loss of efficacy have also been described. In a retrospective study conducted by French investigators,⁴⁷ among the 15 patients who were treated with infliximab (some patients successively received both infliximab and etanercept), 4 of 15 (27%) and 9 of 15 (60%) achieved complete and partial responses, respectively. In the two remaining patients, infliximab therapy was ineffective. At the time of the survey, 10 of the 15 patients treated with infliximab had discontinued the treatment after a mean treatment duration of 9 months because of lack of efficacy (6 patients) or a side effect (3 patients). In the same study, in the 10 patients who were treated with etanercept, only 1 achieved a complete response and 7 of 10 a partial response. More than 120 patients treated with a TNF- α blocker have been reported in the literature, including those in whom it was ineffective. Switch from one TNF- α blocker to another one may be useful. Infliximab may be more effective than etanercept. Experience with adalimumab is limited.^{45,46}

Anakinra

Data from case series indicate that anakinra can control disease activity in patients with AOSD resistant to treatment with other drugs such as glucocorticoids, MTX, or even TNF blockers. Fitzgerald and colleagues⁴⁸ in a seminal study were the first to use anakinra for AOSD. In this open-label study of four patients with AOSD refractory to MTX and also to etanercept, treatment with anakinra in two patients resulted in rapid and complete resolution of both the systemic and articular manifestations that was sustained during a 6- to 14-month follow-up. Recently, in a series of 15 patients with AOSD, at least 50% improvement was seen in 11 patients (73%) at a mean follow-up of 17 months. Finally, in a recent open, randomized, multicenter study of 24 weeks' duration, 22 patients with AOSD who were taking prednisolone received anakinra (n = 12) or a disease-modifying antirheumatic drug (DMARD) (n = 10). At 8 and 24 weeks, 7 of 12 and 6 of 12 receiving anakinra and 5 of 10 and 2 of 10 receiving a DMARD achieved remission. During an open-label extension of 28 weeks, 7 of 14 patients taking anakinra and 2 of 3 taking a DMARD were in remission.⁴⁹ More than 140 patients with AOSD have been treated with anakinra. Anakinra is well tolerated. In some patients a reduction in anakinra injections was possible.^{45,46}

Tocilizumab

Tocilizumab is a humanized anti-IL-6 receptor antibody that specifically blocks the actions of IL-6, a cytokine that is markedly elevated in active AOSD. Several case reports have shown promising results of tocilizumab for AOSD. Most of the patients were resistant to MTX, corticosteroids, and biologic drugs, including anti-TNF blockers and anakinra. French investigators reported 14 patients (9 women and 5 men, mean age of 38.4 years, disease duration of 13.6 years) with refractory AOSD treated with tocilizumab.⁵⁰ All these patients had persistent active arthritis (14/14) or systemic manifestations (7/14) that were resistant to conventional treatment, including MTX (14/14), anakinra (14/14), and anti-TNF- α drugs (12/14). In most patients tocilizumab was administered at a dose of 8 mg/kg every 4 weeks intravenously (as for RA), but four patients received 8 mg/kg every 2 weeks. Tocilizumab was combined with MTX in eight patients and with leflunomide in two. In most patients, response to tocilizumab was rapid and sustained. More than 40 patients with AOSD have been reported to be treated with tocilizumab.^{45,46}

■ **TABLE 87.4**
Criteria sets proposed to identify patients with adult-onset Still disease

	Cush et al. (1987) ⁴³	Yamaguchi et al. (1992) ⁴¹	Fautrel et al. (2008) ⁴²
Design	Single center, retrospective	Multicenter, retrospective	Single center, retrospective
Data analysis	Descriptive	Discriminatory statistical analysis	Logistic regression analysis
Cohort size	21	90	72
Disease duration	11.8 yr	3.8 yr	2.9 yr
Case definition	Fever ≥39°C and arthralgia/arthritis with any 2 of leukocytosis, JRA, rash, serositis/RES involvement	Clinical diagnosis upheld after case review by expert committee	Patients undergoing ferritin measurement and clinical diagnosis upheld after prolonged observation and case review by one expert
Excluded from analysis	RF >1:80 ANA >1:100	Nondefinite cases after review (n = 56)	Nondefinite cases after review
Comparator group	None	267 definite non-AOSD cases	130 definite non-AOSD cases
Criteria set	Fever ≥39°C and arthralgia/arthritis with any 2 of leukocytosis, JRA, rash, serositis/RES involvement	<i>Major:</i> Fever ≥39°C for >1 wk, arthralgia >2 wk, maculopapular nonpruritic salmon-pink rash, leukocytosis ≥10,000/mm ³ with ≥80% neutrophils <i>Minor:</i> Pharyngitis or sore throat, lymphadenopathy and/or splenomegaly, abnormal aminotransferases, negative rheumatoid factor or ANA assay	<i>Major:</i> Spiking fever ≥39°C, arthralgia, transient erythema, pharyngitis, neutrophils >80%, glycosylated ferritin fraction <20% <i>Minor:</i> Typical rash, leukocytosis ≥10,000/mm ³
Required	As above	At least 5 criteria, including 2 major	Four major criteria or 3 major and 2 minor criteria
Exclusion needed	None	Infections, malignancies, vasculitides	None
Sensitivity for set	Not analyzed	96%	81%
Specificity for set	Not analyzed	92%	98%

ANA, antinuclear antibody; AOSD, adult-onset Still disease; JRA, juvenile rheumatoid arthritis; RES, reticuloendothelial system; RF, rheumatoid factor.

Other biologic agents

Limited evidence suggests that rituximab and abatacept may be effective in treating AOSD refractory to other biological agents. Canakinumab, a fully human monoclonal antibody against IL-1β with a half-life of 26 days, is promising. It is used for the management of cryopyrin-associated autoinflammatory syndromes caused by mutations in the NALP3 inflammasome. It has been used successfully in two patients with AOSD resistant to anakinra. Interestingly enough, canakinumab has been shown to be very effective in children with systemic JIA. Rilonacept (IL-1 Trap molecule, a soluble dimeric fusion protein) is another long-acting inhibitor of IL-1. It has been used successfully in four patients with AOSD.^{45,46}

Treatment strategy for adult-onset Still disease

It is essential to keep in mind that therapeutic decisions should be based on the extent and severity of organ system involvement. The main options are NSAIDs, glucocorticoids, MTX, and biologic agents.

NSAIDs should be the initial therapy in patients with mild disease. Most patients will require treatment with glucocorticoids, especially those with fever, joints symptoms, or internal organ involvement. If glucocorticoids are required, we suggest adding MTX because long-term corticosteroid treatment is the rule. Pulse corticosteroid therapy is reserved for patients with life-threatening disease such as pericardial tamponade, myocarditis, diffuse intravascular coagulation, and macrophage activation syndrome. In patients with refractory disease, biologic agents, especially anakinra and tocilizumab, are promising^{45,46} (Fig. 87.4).

Special issues regarding treatment

Pregnancy

Patients with AOSD are at increased risk for adverse outcomes of pregnancy. An increased rate of preterm birth and intrauterine growth retardation and a possible influence of disease activity on pregnancy outcome have been reported. AOSD may occasionally appear during pregnancy. Treatment with glucocorticoids is mandatory. In a patient known to have AOSD, pregnancy should be planned and treatment with immunosuppressors (MTX) stopped. A combined regimen consisting of glucocorticoids and NSAIDs is advisable. In the case of biologic drugs, it is recommended that they be stopped. Successful pregnancy and breastfeeding have been reported in a pregnant patient treated with anakinra.⁵¹

Fig. 87.4 Principal treatment regimens for adult-onset Still disease include NSAIDs, glucocorticoids, MTX, and biologic agents. AOSD, adult-onset Still disease; IL-1, interleukin-1; NSAID, nonsteroidal antiinflammatory drug; TNF, tumor necrosis factor.

Hip involvement

Hip involvement in patients with AOSD is a dramatic issue. The clinician should dismiss the possibility of osteonecrosis, fracture, and actual hip involvement by arthritis. Rapid diagnosis is required. If confirmed, corticosteroid injections are advisable. If the patient is not taking biologic drugs, this is recommended.

Macrophage activation syndrome

Macrophage activation syndrome could be the initial form of AOSD. However, the appearance of this complication during the diagnostic process or evolution of the disease is most common. Clues to the diagnosis are fever, cytopenia, hypertriglyceridemia, and an increase in ferritin and lactate dehydrogenase. The diagnosis should be confirmed by marrow aspirate or bone marrow biopsy. Treatment consists of pulse glucocorticoids, intravenous immunoglobulins, cyclosporine, and biologic drugs (anakinra or tocilizumab).⁵²

AA amyloidosis

AA amyloidosis may complicate the evolution of AOSD. Very occasionally is AA amyloidosis the initial form of AOSD. The most common sign is proteinuria. The diagnosis should be confirmed by abdominal fat, rectal, or kidney biopsy. Treatment with biologic drugs is recommended to halt the evolution to renal failure.^{53,54}

PROGNOSIS AND FUNCTIONAL OUTCOME

Three main patterns are recognized in the course of AOSD. Approximately a third of patients fall into each pattern:

- Monophasic pattern: patients with the monophasic pattern have a disease course that usually lasts less than 1 year, with complete resolution of symptoms. Weaning from drug treatment may take longer.
- Intermittent pattern: patients have two or more disease flares with complete remission between episodes. Subsequent flares tend to be less severe and of shorter duration than the initial episode.
- Chronic pattern: patients with chronic AOSD have persistently active disease associated with destructive arthritis.

Baseline risk factors for the development of chronic disease and an unfavorable outcome are the occurrence of polyarthritis early in the course of AOSD, hip and shoulder involvement, and the need of glucocorticoid therapy for more than 2 years.

The functional status of patients with AOSD is generally good. In one series of 62 patients, 90% were American College of Rheumatology functional class I. In another series of 41 patients, 90% were also class I or II.^{17,30}

Imaging of rheumatoid arthritis

■ THOMAS J. LEARCH

- Symmetric bilateral rheumatoid arthritis (RA) is commonly seen in the hands and feet, but asymmetric disease is frequently found in large joints.
- Hands and feet show the earliest radiographic changes of RA, which include soft tissue swelling, erosions, and diffuse joint space narrowing.
- Radiographic damage to large joints is seen most frequently in the elbow, shoulder, and knee.
- Sacroiliac joint disease in a patient with RA is relatively insignificant and not common.
- Atlantoaxial subluxation and basilar invagination are frequently present. The lateral cervical spine in flexion is the best way to evaluate patients for atlantoaxial subluxation. Basilar invagination is best appreciated on magnetic resonance imaging and computed tomography.

INTRODUCTION

Diagnostic imaging plays an integral role in the diagnosis and follow-up of patients with articular disorders. Patients with unclear and confusing clinical manifestations may have specific imaging findings that allow more accurate and timely diagnosis. For the rheumatologist, diagnostic imaging aids in the clinical diagnosis of rheumatoid arthritis (RA), provides insight into the severity and extent of joint disease, and helps in monitoring response to treatment regimens.

With the increasing use of disease-modifying antirheumatic agents and biologics early in the course of disease, accurate diagnosis, documentation, and staging of disease with imaging studies have become ever more important. Imaging provides an important tool to aid in the early diagnosis of RA and can also be used to evaluate the extent and severity of disease. Imaging studies provide an objective measure of the anatomic damage that defines the course of the disease and the long-term effects of treatment. Imaging studies help in monitoring disease progression or remission and response to therapeutic interventions. Advances in imaging technologies beyond conventional radiography have been dramatic and offer new insight into diagnosis and progression of disease.

APPROACH TO IMAGING AND GENERAL IMAGING FEATURES

The imaging hallmarks of RA are abnormalities in alignment, periarticular osteoporosis that progresses to generalized osteoporosis, bony erosions, uniform joint space narrowing, and periarticular soft tissue swelling with the formation of synovial cysts and rheumatoid nodules. The distribution of changes is generally bilateral and symmetric, especially in the hands, wrists, and feet, where the earliest changes are seen.

Various imaging modalities can be used to study RA. Each modality has strengths and weaknesses, and some are better than others in visualizing various pathologic processes. A generalized approach to analyzing imaging studies for RA has been suggested by Forrester and Brown,¹ who proposed using the mnemonic “the ABCD’s of arthritis”:

- A—Alignment
- B—Bone mineralization

- C—Cartilage and joint space
- D—Distribution
- S—Soft tissues

Changes in alignment are searched for in all imaging studies but are particularly common in the wrists, hands, feet, and craniocervical junction. Abnormalities in alignment may be reduced and minimized when the patient is positioned for posteroanterior radiographs of the hands, but they should be readily visualized on oblique and lateral views, during which the hands are not flattened on the film cassette. Atlantoaxial subluxation is frequently seen only on flexion radiographs, and therefore lateral views of the cervical spine should be obtained with the patient assuming a flexed spine posture.

Bone mineralization is usually normal in all arthropathies except RA. Diffuse osteoporosis is commonly seen in the aging process and with RA. It can also occur as a side effect of certain medications, such as corticosteroids. Disuse and immobilization likewise lead to osteoporosis. Conventional radiographs underestimate early osteoporosis but are positive in advanced stages. This is frequently a subjective finding. Periarticular demineralization is subjectively evaluated by the presence of decreased radiographic density in the osseous structures surrounding a joint space.

Cartilage and joint spaces have the same radiographic density as soft tissues and are therefore not directly visualized on conventional radiographs. Normal joints have a uniform covering of cartilage on their articular ends that correlates with the space seen between the articular surfaces of adjacent bones. Cartilage thinning is inferred on conventional radiographs by the finding of joint space narrowing. Joint space narrowing in RA is diffuse, unlike that in osteoarthritis, in which narrowing occurs along biomechanical vectors of use. As articular cartilage narrows, erosive changes can be seen. Erosions are an important imaging finding that helps confirm the diagnosis of RA and demonstrate the severity of disease. Erosions initially appear at the edge of the joint where cartilage is thinnest and synovium attaches. This is referred to as the “bare area.” Such erosions are also called marginal erosions.

Distribution of the pathology is an important observation because various arthropathies have characteristic areas of involvement well known to rheumatologists. Symmetric bilateral disease is commonly seen in RA, particularly in the hands and feet. However, asymmetric disease is frequently found in large joints.

Soft tissue changes are easily overlooked on radiographs because the eye is naturally drawn toward the more dense osseous structures. Digital conventional radiographs allow adjustment of the window or level on viewing monitors and have led to improved visualization of joint and bursal swelling and effusions. Symmetric swelling about joints in the hands as a result of a combination of effusion, synovial proliferation, and periarticular soft tissue edema is an early finding on conventional radiography. Advanced imaging modalities such as ultrasonography and magnetic resonance imaging (MRI) can be used to optimally resolve any diagnostic difficulties in soft tissue disease.

IMAGING MODALITIES

Conventional radiography

Conventional radiography has long been the mainstay of imaging. It is inexpensive, easily performed, and readily available. Therefore imaging of articular disorders should start with this modality. Well-performed, high-quality radiographs show osseous and soft tissue changes that document

the severity and extent of disease. They often are sufficient, and no further imaging may be required. Follow-up films allow assessment of disease progression or remission.

Hands and wrists

The hands and wrists are commonly involved in RA. The hands (as well as the feet) show radiographic changes the earliest, and the findings are typical.^{2,3} Therefore these studies are frequently obtained during initial evaluation of the disease. All the joints of the wrist and hand can be assessed with one radiographic study, so in the interest of cost savings, hand films only need be requested. Hand films routinely include the wrist joints.

Soft tissue swelling related to joint effusion, synovitis, and periarticular edema is the earliest radiographic change and can be seen at the proximal interphalangeal and metacarpophalangeal (MCP) joints and at the ulnar styloid (Fig. 88.1). Hyperemia and disuse result in periarticular osteoporosis. Erosions are initially very subtle on conventional radiographs and are seen as irregularity of the white cortical line. Erosions occur earliest about the carpus (usually at the pisiform, triquetrum, and ulnar styloid) and second MCP joint.³ Initially, they may have a dot-dash appearance with subsequent progression to frank defects and irregularity. Bare area erosions at the metacarpal head-neck junction and bases of the phalanges follow. These erosions are more prominent at the radial and volar aspect of the metacarpal head. Inflamed synovial-lined tendons can also lead to erosion. This typically occurs at the ulnar styloid secondary to tenosynovitis of the adjacent extensor carpi ulnaris tendon (Fig. 88.2).

As cartilage destruction continues, diffuse narrowing of affected joints becomes evident on conventional radiographs. This is well visualized at the carpal and MCP joints. Normally, these articulations are uniformly 2 mm wide. Comparison with adjacent or contralateral uninvolved joints or previous studies helps in making this finding more obvious.

Joint ankylosis occurs later in the disease process and typically involves the carpus and rarely the interphalangeal joints.

Abnormalities in alignment are most dramatic in the hands and wrists and tend to be symmetric. They are caused by the abnormal kinetic pull of tendons on damaged joints, which produces unbalanced forces that result in characteristic deformities. The carpus deviates radially and translates toward the ulna. On the posteroanterior view the lunate normally articulates

with the lateral aspect of the radius. When more than half the articular surface of the lunate is medial to the ulnar edge of the distal end of the radius, radial deviation and ulnar translation of the carpus have occurred (Fig. 88.3). Characteristic ulnar deviation and palmar subluxation of the MCP joints, boutonnière and swan neck deformities of the fingers, and Z deformities of the thumb are easily assessed clinically and further documented on conventional radiographs (see Fig. 88.3). Such changes in alignment are also associated with systemic lupus erythematosus and Jaccoud arthropathy; however, joint space narrowing, erosions, and inflammation are much more prominent in RA.

Feet and ankles

The forefoot has been reported to show the earliest radiographic changes in patients with RA.³ The lateral fifth metatarsal head is the first area to show erosion. The medial aspect of the first interphalangeal joint is also involved early (Fig. 88.4). Posteroanterior views are best used to assess for early erosions. Oblique views are not necessary and may be overread by inexperienced viewers because the normal facets of the metatarsal heads, exaggerated on this view, may be falsely interpreted as erosions.

Diffuse joint space narrowing of the ankle and tarsal articulations is seen frequently. Effusions involving the ankle joint and retrocalcaneal bursa effusions are readily appreciated on lateral conventional radiographs (Fig. 88.5). As in the carpus, the tarsal joints may become fused in advanced disease.

Abnormalities in alignment similar to those seen in the hand occur in the forefoot. Fibular deviation of the toes and dorsolateral subluxation or dislocation of the proximal phalanges at the metatarsal head are common. The fifth toe may be relatively spared.

Large joints

In patients with long-term RA, radiographic damage to the large joints is seen most frequently in the elbow, shoulder, and knee, with reported rates of 32%, 31%, and 27%, respectively. This is followed by the subtalar, ankle, and hip joints, with reported rates of 24%, 22%, and 21%, respectively.⁴ In general, the distribution of the arthropathy is bilateral and symmetric, especially in the small joints of the hands and feet. With involvement of large joints, symmetry is less common.

Fig. 88.1 Early rheumatoid arthritis. Mild pancarpal and third through fifth metacarpophalangeal (MCP) joint space narrowing is present. The second MCP joint is not narrowed, but note the soft tissue fullness (arrows) radial to the joint secondary to pannus and joint fluid. Soft tissue fullness is also present near the distal end of the ulna (arrowheads) secondary to tenosynovitis of the extensor carpi ulnaris.

Fig. 88.2 Erosive disease is present at the ulnar styloid and bare areas of the second metacarpophalangeal joint (arrowheads). Note the erosive changes of the radial aspect of the second metacarpal head with interruption of the white cortical line as opposed to the intact third metacarpal head. This is a Korean patient who used acupuncture to treat her rheumatoid arthritis. Note the acupuncture needle tips (arrows) that were left in the patient's soft tissues.

Fig. 88.3 Radial deviation and ulnar translation of the carpus with the majority of the lunate no longer articulating with the radius. Palmar subluxation and ulnar deviation of the metacarpophalangeal joints and a swan neck deformity of the fifth digit are apparent.

Fig. 88.4 Radiograph of the foot demonstrating erosions of the third through fifth metacarpal heads with associated narrowing of the metatarsophalangeal joint space. There is also narrowing of the first interphalangeal joint space with bare area erosions.

Fig. 88.5 Lateral hindfoot. The Achilles tendon is thickened at the insertion of the calcaneus (white arrows) secondary to retrocalcaneal bursitis. Note the associated erosions and irregularity of the posterior calcaneus (arrowheads). Ankle joint effusion is present (black arrows).

Pelvis and hips

Soft tissue changes about the hip such as joint effusion and greater trochanteric and iliopsoas bursitis are not readily appreciated on conventional radiographs. These findings usually require advanced imaging modalities. The hallmark of RA of the hip on conventional radiographs is diffuse joint space narrowing with erosions of the femoral head and neck (Fig. 88.6). Later in the disease process the erosions may greatly deform and whittle the femoral head. Thinning and erosive disease of the acetabular surface leads to protrusion of the femoral head and acetabulum into the pelvis, a condition called protrusio (Fig. e88.1).

Sacroiliac joint disease in RA is relatively insignificant and not commonly observed on imaging studies. The sacroiliac joints are not generally radiographically abnormal until late in disease, when asymmetric narrowing, erosions (predominantly on the iliac side because its articular cartilage is thinner than in the sacrum), and possibly areas of fusion may be seen.

Knee

This large synovial joint is frequently affected by RA. Early radiographic findings include joint effusion with engorgement of the suprapatellar bursa (seen best on lateral radiographs), pancompartmental joint space narrowing, and bare area erosions (Fig. 88.7). As ligamentous laxity ensues, varus or valgus deformities develop. Later in disease, osteophytosis related to secondary osteoarthritis can be seen. Popliteal cysts are commonly noted on advanced imaging studies but are rarely identified on conventional radiography.

Shoulder

Early in disease, marginal erosions are seen in the rotator cuff attachments at the superolateral aspect of the humeral head, where cartilage is the thinnest—the bare area of this joint. This is followed by diffuse glenohumeral joint space narrowing as loss of cartilage continues (Fig. 88.8). The joint space narrowing may be difficult to appreciate on routine anteroposterior shoulder radiographs because the glenohumeral joint is not in profile. The Grashey view, obtained with the patient in 30 to 40 degrees of posterior oblique positioning of the torso, provides a perpendicular profiled view of the joint and is more sensitive in identifying joint space narrowing. Glenohumeral joint effusions are not detected on conventional radiographs.

In more chronic disease, rotator cuff atrophy and tearing result in superior migration of the humeral head, narrowing of the acromiohumeral distance to less than 7 mm, and eventual mechanical pressure erosion caused by contact of the uncovered humeral head with the undersurface of the acromion. Erosive changes about the acromioclavicular joint occur with later resorption of the distal end of the clavicle (Fig. e88.2).

Fig. e88.1 Advanced disease of both hips. The right femoral head is eroded superiorly, and an acetabular protrusio deformity with marked thinning and a resultant fracture is present. The left hip demonstrates diffuse joint space narrowing with a large subchondral cyst present in the superior acetabulum (arrows).

Fig. e88.2 Advanced erosive disease of the glenohumeral joint. Note the erosive changes involving the distal end of the clavicle. The humerus is high riding secondary to a rotator cuff tear and atrophy. The bones are markedly osteopenic with an insufficiency fracture of the acromial spine (arrows).

Fig. 88.6 Diffuse narrowing of the left hip joint space with small erosions of the femoral head. Note the linear sclerotic area of the pubis (arrows) related to an insufficiency fracture.

Fig. 88.7 Diffuse joint space narrowing involving both medial and lateral compartments bilaterally. Multiple erosions are present at the articular surface and the bare areas of the knee joint.

Elbow

The elbow is frequently involved in RA, and indeed, this is the most common arthritis affecting this joint. Soft tissue changes are the early radiographic findings and include joint effusion with displacement of the anterior and posterior fat pads away from the humerus and soft tissue swelling posterior to the olecranon corresponding to olecranon bursitis. Diffuse joint space narrowing secondary to cartilage loss and articular erosions occurs in both the radiocapitellar and ulnotrochlear compartments (Fig. 88.9). It may become quite severe with marked articular bone loss and subluxation. Other synovium-lined areas about the joint may be involved by synovitis and pannus as well (Fig. 88.10).

Cervical spine

Spinal disease in RA occurs most frequently in the cervical spine, with more than half of all patients with RA experiencing involvement in the course of their disease. Most patients with severe RA will have abnormalities in this area. The most common abnormality is atlantoaxial subluxation, followed by basilar invagination.^{5,6}

The most important radiograph in the cervical spine series is the lateral radiograph with the patient assuming a flexed position. The diagnosis of atlantoaxial subluxation, which is difficult to discern on physical

Fig. 88.8 Diffuse glenohumeral joint space narrowing with multiple erosions (arrows). Note the large erosion just medial to the greater tuberosity (arrowhead). This is the bare area of the shoulder, where the earliest erosions are seen.

Fig. 88.9 Diffuse elbow joint space narrowing with erosions. The trochlea is much more eroded than the capitulum. Displaced fat pads are present (arrows) secondary to joint effusion.

examination, is made easily with this projection (Fig. 88.11). Normally, the distance between the anterior arch of C1 and anterior aspect of the dens of C2 is less than 3 mm in adults and less than 5 mm in children. Subluxation greater than 8 mm usually requires surgical intervention. The anterior C1-C2 area may be obscured because of cranial settling or basilar invagination. Atlantoaxial subluxation can still be diagnosed by evaluating the posterior cervical line. This is a radiographic line drawn between the spinal lamina of C1, C2, and C3 and should be straight. Anterior subluxation of the C1 lamina reflects the same degree of anterior subluxation of the atlantoaxial articulation (see Fig. 88.11). Mid and lower cervical laxity allows anterior listhesis of the vertebral bodies, which results in a stepladder appearance on the lateral flexed radiograph. The flexed view also permits better visualization of the synovial facet joint surfaces as they open. Fusion of the facet joints may occur at some levels, but multilevel posterior ankylosis is rare in adult-onset RA. Basilar invagination may be diagnosed on conventional radiographs but is best studied with MRI or computed tomography (CT).^{7,8} This allows visualization of the adjacent brain stem and spinal cord, which may be impinged by the dens (Fig. 88.12). Advanced imaging also demonstrates associated pannus and erosions about the dens.

Arthrography

Diagnostic arthrography was previously used to evaluate intraarticular structures, the joint capsule, and surrounding ligaments but has largely been replaced by MRI and ultrasonography. It is rarely used today in the

Fig. 88.10 This patient was found to have a mass in her elbow. Axial T1-weighted magnetic resonance imaging with fat saturation after intravenous gadolinium enhancement demonstrates enhancing synovium in the bicipitoradial bursa (arrowheads) where the biceps tendon (arrow) inserts on the radius (R). Conventional radiographs of the hands demonstrated changes consistent with rheumatoid arthritis. This was the patient's initial findings.

Fig. 88.11 Atlantoaxial subluxation. The anterior arch of C1 is displaced 8 mm anterior to the dens. This is confirmed by the abnormal posterior cervical line.

evaluation of patients with RA. Image-guided injection and aspiration of joints, however, still play an important role in the injection of corticosteroids or other medications directly into a specific location and in the diagnosis of rheumatoid joints complicated by infection.

Many of the classic imaging features of RA overlap considerably with septic arthritis, and this differential diagnosis needs to be considered.^{9,10}

Fig. 88.12 A sagittal T2-weighted magnetic resonance image of the craniocervical junction demonstrates basilar invagination with superior migration of the dens through the foramen magnum. The dens is indenting the medulla.

Septic arthritis is usually a monoarticular disease. However, it must be kept in mind that patients with RA are at increased risk for septic arthritis as a result of immune suppression and that previous damage to joints during the course of the disease makes these joints more prone to infection.¹¹ Because septic arthritis is such a catastrophic illness, prompt aspiration of these joints is essential in the evaluation and diagnosis of these patients. Cadaveric joint arthrocentesis studies performed by senior emergency medicine residents have shown success rates of 80% for accurate positioning of needles in various joints.¹² Because imaging guidance is not routinely used by orthopedic, rheumatology, or emergency physicians, radiologists are frequently requested to aspirate or inject joints. By using fluoroscopic or ultrasound guidance, deep, difficult-to-palpate joints such as the hip or shoulder can easily be accessed. During this procedure, contrast medium is injected into the joint to yield additional information on surrounding synovial cyst formation and the presence of sinus tracts (Fig. e88.3). Image guidance offers the distinct advantage of directed needle placement and imaging proof that the sample obtained did indeed come from the joint itself.

Ultrasonography

Ultrasonography is a readily available and relatively low-cost modality that has increasingly gained wide acceptance in the evaluation of patients with RA, particularly in Europe. In experienced hands, ultrasonography can be used to evaluate soft tissue structures and demonstrate fluid collections and muscle and tendon integrity. It is used for evaluation of muscle/tendon subluxations, dislocations, and tears and tenosynovitis. It can be done in real time with patient movement, and the contralateral side can be imaged quickly for comparison. Fluid collections such as abscesses, popliteal and other synovial cysts, bursae, ganglia, and joint effusions are all well imaged (Fig. 88.13). Under direct ultrasound guidance these collections can be aspirated or injected with medication.

Ultrasound beams cannot penetrate bone, so intraosseous lesions and some intraarticular areas cannot be imaged. Ultrasonography, however, has increasingly been used to study articular surface cartilage abnormalities, particularly in the evaluation of early erosive disease, and has higher sensitivity in detecting erosions than conventional radiography does.¹³

Fig. e88.3 Arthrogram of a septic right hip joint demonstrating a sinus tract (arrows) exiting the inferolateral aspect of the thigh.

Fig. 88.13 Longitudinal ultrasound image anterior to the knee along the patellar tendon. A large fluid collection (black arrows) is located anterior to the patellar tendon (arrowheads) in the prepatellar and infrapatellar bursae along with areas of synovial hypertrophy (white arrows). P, patella; T, tibial tuberosity.

Ultrasonography has been shown to be highly sensitive in assessing bone destruction and inflammation in finger joints, with high correlation to MRI studies done concurrently.¹⁴ The main limitation of ultrasonography, however, remains the steep learning curve in performance of subspecialized examination protocols. Additionally, many hospitals and imaging facilities, especially in the United States, may not have radiologists familiar with musculoskeletal ultrasonography.

Computed tomography

Since the development of CT in the 1970s, it has been used extensively to image osseous structures. Most imaging was generally performed in the transverse plane, with computer reformatted images in other planes lacking resolution and detail. Imaging of muscle, ligaments, and joint structures was limited and considered insufficient. Imaging of metallic orthopedic hardware and joint replacements caused considerable artifact, thereby limiting the usefulness of CT in many musculoskeletal cases.

However, recent developments in multidetector CT technology and computer-enhanced reformatting of image data have revolutionized this modality and broadened its use. Images are still generally obtained in the transverse plane, but reformatted images in other planes can now be obtained immediately on advanced workstations to allow visualization of structures in any linear or even curvilinear plane. Soft tissue resolution in many areas now rivals that of MRI and ultrasonography. With intraarticular injection of a contrast agent, articular structures such as menisci and cartilage are well demonstrated. Decreased streak artifact from metal now permits detailed imaging of joint arthroplasties and other orthopedic hardware.

CT optimally images osseous structures and can easily detect erosions. It is more sensitive than MRI in the detection of early erosions in the hand.¹⁵ CT is often used in the preoperative evaluation of patients for joint arthroplasty because of its optimal assessment of bone stock, articular surfaces, and version. Postoperative evaluation of hardware positioning and complications is also now possible (Figs. 88.14 and 88.15).¹⁶ CT arthrography (done after injection of a contrast agent into the joint) assesses intraarticular structures and cartilage surfaces.¹⁷ It has been used increasingly in patients who cannot tolerate or have absolute contraindications to MRI.

Magnetic resonance imaging

MRI is unique in its ability to optimally image bone, articular structures, and soft tissues, with the added advantage of not using ionizing radiation. Initially used to evaluate large joints such as the hips, knees, and shoulders, new developments have improved the ability of MRI to resolve smaller joints and structures, thus furthering its application in the diagnosis and evaluation of patients with RA.

MRI is generally well tolerated by all patients except those with claustrophobia, although open scanners and medications have substantially decreased this problem; by the disoriented or confused, who may not tolerate the inherent noise that the scanner produces or may not be able to stay still during sequence acquisitions; or by the morbidly obese, where weight limitations may hinder tabletop movement and positioning. Some relative and absolute contraindications to MRI exist and preclude its use in some patients. All patients are screened before the procedure to determine any

Fig. 88.14 Coronal reformatted computed tomographic image of a patient with a total hip replacement. There is marked wear of the polyethylene cup superiorly, with the femoral head component now in contact with the metal acetabular cup. The interface between the native acetabulum and acetabular cup is markedly widened, which has resulted in a loose, floating prosthetic cup. Protrusio deformity is present.

Fig. 88.15 Computed tomographic arthrogram of a total shoulder replacement. Intraarticular contrast medium surrounds the dislocated polyethylene glenoid component (arrow).

potential contraindications. A common misconception is that patients with joint replacements or other orthopedic hardware cannot undergo MRI. In fact, MRI has been used increasingly to evaluate painful or infected arthroplasties, and newer sequences can minimize metallic artifact. If there is any concern that the patient cannot be in a high magnetic field environment,

other imaging strategies such as ultrasonography or CT may be recommended by the radiologist.

MRI has long been advocated for the evaluation of internal joint derangement. To this end, it can superbly image ligaments, tendons, menisci, articular cartilage, synovium, and joint fluid (Figs. 88.16 and 88.17; also see Fig. 88.10).

Structures surrounding articulations such as musculature and the spinal cord are well delineated. MRI is the modality of choice for evaluating the cervicocranial junction for atlantoaxial subluxation and basilar invagination and their effects on the adjacent spinal cord and brain stem (see Fig. 88.12). In patients with symptomatic cervical spine involvement, there is a strong correlation between the development of neurologic dysfunction and MRI identification of atlantoaxial spinal canal stenosis, especially in those with evidence of upper cervical cord or brain stem compression and subaxial myelopathic changes.¹⁸

Fig. 88.16 Axial gradient-echo magnetic resonance image of the shoulder in a patient with rheumatoid arthritis complaining of a mass. A large synovial cyst (white arrows) has dissected along the long head of the biceps tendon (arrowhead). Pannus (black arrows) is present in the glenohumeral joint along with marked irregular erosive change of the glenoid (G).

Fig. 88.17 Sagittal fat-saturated proton density-weighted magnetic resonance image of the shoulder demonstrating large chronic subacromial or subdeltoid bursal fluid inflammation and rice body formation (arrows). Erosion (arrowhead) is present in the humeral head.

MRI is also the modality of choice for imaging bone marrow abnormalities. In patients with RA, bone infarction, bone marrow edema adjacent to synovial inflammation, and occult traumatic and insufficiency fractures are all optimally imaged with this modality.

MRI clearly demonstrates early disease before conventional radiography does. Since medical therapy for RA has become increasingly more effective, early diagnosis and assessment of disease activity and joint damage have become ever more important. MRI has also been used to detect early synovitis and to quantify early marginal erosions, joint effusion, and cartilage disease, which are frequently radio-occult (Fig. 88.18).¹⁹ MRI has been shown to detect erosions years before their appearance on conventional radiographs²⁰ and is more sensitive than ultrasonography.²¹

Hence MRI can play an important role in diagnosis, prognosis, and monitoring of the effectiveness of therapies in clinical practice. However, although erosions, synovitis, and tenosynovitis in the hands are frequently encountered in early RA and are well demonstrated by MRI, these findings are not specific. They can also be seen in patients with systemic lupus erythematosus and primary Sjögren syndrome.²²

The main limitation of MRI is expense and availability; however, the modality is now in most hospitals and many outpatient facilities, and its more ubiquitous presence may reduce the cost. Its effectiveness in early diagnosis of disease has led to increasing use at the onset of disease. Cost-saving measures can be used and are advocated by radiologists familiar with early disease. This may include scanning both wrists and hands together in the prayer position with the patient lying on the side and hands above the head. The right hand can be labeled with a dedicated MRI marker to avoid confusion, and simultaneous imaging of both sides can be performed to obtain a “two for one” study.

As good as 1.5-T MRI is, newer high-field-strength (3.0-T) imaging can provide even more detailed resolution of smaller structures. Currently, 3.0-T imaging is becoming increasingly available at the university and community level. These magnets produce more detailed imaging studies, and they are particularly useful in neuroradiology. Although musculoskeletal examinations are generally of higher quality with 3.0-T magnets, which improve evaluation of the extent of bone edema and synovitis and identification of small bone erosions by 14% to 22%, acceptable image quality is still achieved with 1.5 T.²³

As further developments in MRI technology, protocols, and research improve our understanding and ability to image rheumatic diseases, this modality will undoubtedly play an important role in diagnosis, prognosis, and monitoring of the effectiveness of therapies in clinical practice.

Fig. 88.18 Coronal T1-weighted magnetic resonance image of the wrist demonstrating multiple carpal erosions. These erosions were not seen on radiographs.

The contribution of genetic factors to rheumatoid arthritis

■ ROBERT M. PLENCE

- Twin and family studies have confirmed an important contribution of genetic factors to the development of rheumatoid arthritis.
- Genes encoded within HLA-DRB1 from the major histocompatibility complex have provided the most consistent evidence of an effect.
- Recent studies covering the whole genome have suggested a number of other candidate genes.
- The effects of key genes, including HLA-DRB1, are modified by environmental factors, particularly smoking.

INTRODUCTION

This chapter endeavors to summarize the wealth of information that has emerged on the contribution of genetic factors to rheumatoid arthritis (RA). The first associations of genetic factors with RA were described more than 4 decades ago, but the rate of progress in recent years has been exponential. This chapter summarizes the strength of the evidence suggesting a role for genetics in susceptibility to RA. A detailed analysis of the role of both HLA and other loci within the major histocompatibility complex (MHC) is presented. Much of the most recent data has come from studies outside the MHC and is based on emerging powerful technologies. Finally, the evidence for gene-environmental interactions is reviewed briefly.

STRENGTH OF GENETIC CONTRIBUTION

Early evidence for a genetic component in RA was derived from family and twin studies.^{1,2} The risk for RA is 0.5% to 1% in the general population, but a monozygotic twin of a patient with RA has a risk of around 15%.³⁻⁵ Moreover, the relative risk (RR) to the sibling of a proband with RA (known as λ_s) is approximately 5 for RA,⁶⁻⁸ although the number varies depending on the population studied.⁹ A complementary approach for estimating the genetic component is to consider the heritability of a disease, which is the proportion of the variance of the disease that is explained by the inherited genetic variance. Using data on twins, the heritability of RA has been estimated to be about 60%, thus indicating that genetic factors account for a large proportion of the population's liability to the disease.¹⁰ However, this serves as only an estimate because measures of heritability may overestimate the genetic component because of the common environment shared by family members or even underestimate the genetic component because of complex genetic interactions (e.g., gene-gene or gene-environment interactions).

ROLE OF MAJOR HISTOCOMPATIBILITY COMPLEX GENES

In common with many other autoimmune diseases, much genetic research has revolved around genes within the MHC region on chromosome 6. The MHC region is the most gene-dense region in the mammalian genome, and it plays an important role in the immune system, autoimmunity, and reproductive success. In humans, the 3.6-megabase pair (Mb) MHC region contains more than 180 expressed genes, about half of which are of known immunologic function. The genes that have garnered the most attention have been the class II human leukocyte antigen (HLA) genes.

History

Over the past 4 decades, many genetic studies have demonstrated the importance of the MHC region in susceptibility to RA. In 1969 it was noted that lymphocytes from patients with RA were poorly reactive when incubated together in mixed lymphocyte culture (MLC).¹¹ In the early 1970s, weak and variable associations between RA and genes in the HLA class I region were described with the use of serologic reagents. More rapid progress was made, however, when techniques became available for testing HLA class II antigens. The earlier MLCs were further refined in 1976, and an association between RA and MLC type Dw4 was described.¹²⁻¹⁴ Thereafter, a serologically defined marker, HLA-DR4, was found to be associated with RA in white populations in the United States. Combining MLC and serologic techniques distilled the RA association to a few specific alleles, namely, DR4 Dw4, DR4 Dw14.1, DR4 Dw14.2, and DR4 Dw15. These techniques were superseded in the 1990s by various DNA-based techniques that provided much greater precision (Fig. 89.1). It was recognized that the MLC and serologic markers just listed represent alleles that change the amino acid sequence of the HLA-DRB1 gene. These alleles were subsequently renamed HLA-DRB1*0401, *0404, *0408, and *0405, respectively. Overall, it has been estimated that the MHC region accounts for approximately a third of the overall genetic burden of RA.^{7,15}

THE SHARED EPITOPE HYPOTHESIS

With the advent of sophisticated DNA typing for HLA-DRB1 alleles, it was noted that not all HLA-DR4 alleles are associated with RA and that different alleles confer risk for RA in different ethnic populations.¹⁶⁻²⁷ The most common (>5% frequency in the population) HLA-DRB1 susceptibility alleles include *0101, *0401, and *0404 in individuals of European ancestry and *0405 and *0901 in individuals of Asian ancestry; less common alleles include *0102, *0104, *0408, *0413, *0416, *1001, and *1402. The classic shared epitope (SE) alleles may not contribute to risk in African American and Hispanic American RA populations,^{28,29} and other HLA-DRB1 alleles may be associated with protection against RA (DRB1*0103, *0402, *0802, *1302).²⁷ (See Table 89.1 for these and other important allelic associations.)

In 1987 Peter Gregersen and coworkers³⁰ proposed an elegant hypothesis for these complex and diverse associations. They showed that RA risk alleles share similarities in a key sequence of five amino acids at residues 70 to 74 in the third hypervariable region of the HLA-DRB1 gene (⁷⁰QRRRAA⁷⁴, ⁷⁰QRRRAA⁷⁴, ⁷⁰QRRRAA⁷⁴). These residues are important in peptide binding, and thus it is hypothesized that RA-associated alleles bind specific peptides, which in turn facilitates the development of autoreactive T cells. These alleles are now widely known collectively as SE alleles (Fig. 89.2). Of note, the *0901 allele observed in Asian populations does not strictly conform to the SE amino acid sequence motif (⁷⁰RRRAE⁷⁴).

Although SE susceptibility alleles are often considered as a group, the strength of the genetic association with susceptibility to RA differs between the individual DRB1 alleles.³¹ There are at least two classes of SE risk alleles (high and moderate). In general, DRB1*0401 and *0405 alleles exhibit a high level of risk, with an RR of approximately 3. The DRB1*0101, *0404, *0901, and *1001 alleles exhibit a more moderate RR in the range of 1.5.

It is becoming increasingly clear that HLA-DRB1 SE alleles largely influence the development of seropositive RA and, more specifically, anti-cyclic citrullinated peptide (CCP)-positive RA.^{32,33} Collectively, SE alleles have an odds ratio of greater than 5 if patients with anti-CCP+ RA are compared with matched healthy controls. Because these alleles are quite common in the general population (together, an allele frequency of approximately 40% in individuals of European ancestry), the attributable risk in individuals with SE alleles is quite high.

Fig. 89.1 The left panel illustrates HLA typing with sera that recognize alloantigens. These sera often recognize broad antigenic specificities, such as DR4, which are epitopes present on a number of different alleles. Finer discrimination is frequently obtained through cellular typing, as schematized in the second panel. In this case, mixed lymphocyte culture of T cells of unknown HLA type is used to measure proliferation on responder cells of known HLA type. In this way, “subtypes” of DR4 are defined: Dw4, Dw10, Dw14, and others. Currently, most laboratories use oligonucleotide typing, as outlined in the third panel. Based on the known nucleotide sequence of different alleles, synthetic labeled oligonucleotide probes are designed that hybridize specifically to the DNA sequence unique to the gene of interest. In some cases a series of oligonucleotide probes are required to distinguish among the different alleles, and a “matrix” approach can be used. In this way even minor differences among alleles can be recognized; for example, this has led to the identification of more than 20 different DR4+ alleles.

TABLE 89.1
Rheumatoid arthritis: HLA-DRB1 alleles conferring susceptibility

	DRB1 susceptibility allele	Epitope sequence	Prevalence in RA (%)	Relative risk
Whites	*0401 (DR4, Dw4)	LLEQKRAA	50	6
	*0404 (DR4, Dw14)	LLEQRRAA	30	5
	*0101 (DR1, Dw1)	LLEQRRAA	24	1
Japanese	*0405 (DR4, Dw15)	LLEQRRAA	71	3.5
Yakima	*1402 (DR6, Dw16)	LLEQRRAA	83	3.3
Israeli Jews	*0101 (DR1, Dw1)	LLEQRRAA	28	6

Summary of the important HLA-DRB1 alleles conferring susceptibility to RA in different ethnic populations. Their approximate prevalence in patients with rheumatoid arthritis in each population, along with relative risk, is listed. Each of these alleles includes the shared epitope (or a close variation), even though the sequence of the remainder of the DRB1 gene may be quite varied among these alleles.

Biologic function of shared epitope alleles

If the SE is important in predisposing to RA, how might it work? Despite more than 3 decades of research, the answer is not completely clear.

The SE region constitutes a helical domain that forms one side of the antigen-binding site, thus suggesting functional significance and an ability to influence the nature of potentially arthritogenic peptides (Fig. 89.3). In

keeping with the hypothesis, alleles that negatively associate with RA have substitutions of amino acids within the SE that would exert a profound influence on the attributes of any bound antigenic peptide. For example, DRB1*0402 and *0103 alleles have a ⁷⁰DERAA⁷⁴ motif, which would have a marked impact on the peptide-binding properties of the molecule.³⁴ Fascinatingly, canine RA (a spontaneous condition affecting dogs that resembles human RA) is associated with dog MHC DRB1 alleles that also have the QRRAA sequence in the third hypervariable region.³⁵ A study from France suggested that the amino acid sequence RAA at positions 72 to 74 is the key sequence in increasing susceptibility to RA and that this is modulated by amino acids at positions 70 and 71.³⁶

Three predominant biologic models have been proposed to explain this association. Each model centers around the interaction between the T-cell receptor (TCR) and class II MHC molecules (Fig. 89.4).

1. HLA molecules are important in selection and establishment of the antigen-specific T-cell repertoire. Interactions with HLA molecules instruct the T cell to differentiate between self and nonself.^{34,37} T cells that show self-reactivity are deleted or inactivated, whereas others are positively selected to establish a repertoire of cells capable of recognizing foreign antigen in the context of self-MHC. It is possible that the SE assists in some way in the positive selection of autoreactive T cells, with a subsequent breakdown in self-tolerance such that the immune system reacts against the body's own constituent parts.
2. As mentioned, the primary role of HLA molecules is to bind peptide and present it to antigen-specific T cells. The location of the SE in a critical area of the binding site of the HLA-DR molecule would influence the nature and orientation of processed peptides that might bind there and thus exert an impact on the trimolecular complex of the HLA-DR molecule, bound peptide, and TCR. Binding to an arthritogenic peptide (e.g., a processed microbial antigen) might initiate and sustain a pathologic immune response. To date, no peptide has been identified that could be recognized by a T-cell clone in the context of all the HLA-DR molecules that associate with RA. However, some mutated variants of naturally occurring peptides have a pattern close to that needed, which suggests that this model is a possibility.^{34,38,39}
3. In a similar fashion to some of the mechanisms that have been proposed for the association between HLA-B27 and spondyloarthritis, “molecular mimicry” may occur in which similarities between the SE and foreign protein might break self-tolerance and generate autoreactive T-cell clones, which eventually leads to RA. Some amino acid sequences from HLA molecules share homology with those from potentially antigenic proteins derived from infectious agents.⁴⁰

Limitations of the shared epitope hypothesis

However, the veracity of the SE hypothesis has been challenged. A number of observations do not fit comfortably with a straightforward pathogenic association between the SE and RA:

- In all populations that have been studied, a variable but substantial minority of individuals with RA do not possess the SE.^{21,41,42}
- Some ethnic populations do not demonstrate a significant association with SE alleles and risk for RA, such as African Americans,^{43,44} whereas others have shown associations with DR markers that do not possess the SE (e.g., HLA-DR3 in Arabs).⁴⁵
- Not all SEs are the same, with a hierarchy of risk attached to the associations with different HLA-DRB molecules. For example, the *0401 allele shows a much greater association with RA than *0101 does, particularly when *0401 is inherited in combination with *0404 (Table 89.2).⁴⁶⁻⁴⁹
- The *0404 and *0405 alleles have an identical SE sequence (⁷⁰QRRAA⁷⁴) yet have different effect sizes (as measured by the odds ratio [OR]).³¹
- The MHC is an extraordinarily gene-rich area in which other loci in close proximity to the HLA-DRB1 gene might exert an impact on predisposition to disease. This complexity is considered in further detail below.
- If the pathogenic process in RA is a simple presentation of arthritogenic peptide, this would intuitively fit with a dominant mode of inheritance. However, the distribution of the SE genotype fits better with a multiplicative mode of inheritance.^{15,50-52} In keeping with a multiplicative mode of inheritance, concordance rates in siblings sharing two HLA haplotypes are double those of siblings sharing one or no haplotypes.^{53,54} It has been argued that having two copies of the SE could influence the downstream T-cell response through earlier effects in modeling the T-cell repertoire.⁵⁵

Fig. 89.2 Sequences of HLA-DRB1 alleles that do or do not confer susceptibility to rheumatoid arthritis (RA) in different populations. (a) At the top are listed the sequences of the DRB1 alleles known to confer susceptibility to RA, with the shared epitope highlighted. The single-letter amino acid code defined at the bottom of the figure is used. Under these sequences are listed very similar sequences from closely related DRB1 alleles that do not confer susceptibility to RA. The lower portion of part (a) contrasts the sequences of other more distantly related DRB1 alleles that are now known to confer susceptibility to RA. The shared epitope occurs only in susceptibility alleles and does not occur in nonsusceptibility alleles, even when their “background” sequence is very similar or identical to that of the susceptibility alleles. (b) Schematic representation of how the amino acid sequence of the first domain of DRB1 relates to the three-dimensional conformation of the final molecule. Red-highlighted arrows correspond to the clustered hypervariable sequences in the DRB1 regions shown above, thus illustrating that the shared epitope constitutes part of the α-helical “wall” of the antigen-binding groove.

Refining the shared epitope hypothesis—the “binding groove” hypothesis

Given the limitations of the SE hypothesis, additional research has been undertaken to refine the model. A study published in 2012 offered a refined view of the SE hypothesis.⁵⁶ Using genome-wide single-nucleotide polymorphism (SNP) data and a novel computational strategy to impute amino acid polymorphisms in HLA-A, HLA-B, HLA-C, HLA-DPA1, HLA-DPB1, HLA-DQA1, HLA-DQB1 and HLA-DRB1, conditional and haplotype analyses identified three amino acid positions (11, 71, and 74) in HLA-DRB1 and single-amino acid polymorphisms in HLA-B (at position 9) and HLA-DPB1 (at position 9) that could almost completely explain the MHC association. These variants account for about 13% of the overall risk for RA in the populations studied.

Interestingly, all five amino acids are located in the peptide binding grooves of the three different HLA molecules. This has led to the “binding groove” hypothesis because the location of these positions within the peptide binding grooves implies a functional impact on antigenic peptide presentation to T cells, either during early thymic development or during peripheral immune responses. The presence of class I and II MHC alleles implicates both CD8+ cytotoxic and CD4+ helper T cells in the pathogenesis of RA.

MAJOR HISTOCOMPATIBILITY COMPLEX: DISEASE SUSCEPTIBILITY OR SEVERITY?

Irrespective of the limitations of the SE hypothesis, the MHC region demonstrates the strongest association with RA and in different family studies

Fig. 89.3 Location of important polymorphic residues with the rheumatoid arthritis-associated “shared epitope.” A ribbon diagram of a DRA/DRB1*0401 molecule is presented and viewed while looking down from above (a) and from the side (b). Amino acids 67, 70, 71, and 74, the residues noted from sequence comparisons and from site-directed mutagenesis analysis to be critical in function of the “shared epitope,” are shown pointing into or out of the peptide-binding groove. Residues pointing into the groove are important in binding peptide, whereas those pointing out of the α -helix are hypothesized to interact directly with the T-cell receptor. Na, Nb, N-terminal residues of the α and β chains.

is the locus that has most consistently demonstrated genetic linkage.^{9,57,58} However, a debate has been generated regarding whether the HLA association is more important in predisposing to RA or in determining disease severity.

For more than 20 years, studies have shown that the HLA-DRB1 alleles are more frequently observed in patients with more severe disease. Clinically, RA is very heterogeneous: some patients have mild, self-limited disease, whereas others have severe multisystem disease. It is entirely plausible that genetic heterogeneity underlies such clinical heterogeneity. Studies in the 1980s suggested that the serologically defined HLA-DR4 association was not observed in community surveys, which presumably represents milder RA.⁵⁹ Conversely, the HLA-DR4 association was very marked in patients with severe articular disease or extraarticular manifestations, such as Felty syndrome.⁶⁰ With the increasing sophistication of molecular typing, it was demonstrated that the SE did not associate with recent-onset inflammatory arthritis.⁶¹ At the opposite end of the clinical spectrum, a meta-analysis of rheumatoid vasculitis⁶² and a review of the extraarticular manifestations of RA⁶³ confirmed the importance of the SE in associating with more severe disease. Multivariate analyses have indicated that presence of the SE predicts erosions at initial diagnosis of RA, as well as an erosive outcome at 3 years.⁶⁴⁻⁶⁷

The question remains: are SE alleles predictive of RA risk or RA severity? Genetic association studies alone may not be able to resolve this question. It could be that more severe disease is more likely to develop in patients with a greater genetic burden of disease, regardless of which alleles predispose to RA. Alternatively, it may be that non-SE genetic factors predispose to risk whereas the SE predisposes to severity. However, all genetic factors

Fig. 89.4 The key role of polymorphic amino acid residues in the HLA molecules associated with disease indicates that intimate contacts between these amino acids and antigenic peptides or the T-cell receptor (TCR), or both, are important genetically regulated triggering events in autoimmunity. In model 1, the polymorphic HLA molecule, in combination with a bound self-peptide, has a key selection role, presumably during the thymic development of maturing T cells. An immature T cell “tests” its receptor specificity before leaving the thymus; suitable recognition and stimulation by the HLA molecule at this point are postulated to lead to maturation and expansion of the T-cell specificity, which in an appropriate context, may be potentially autoreactive. In model 2, a similar recognition event occurs in the peripheral immune system between a mature T cell and an HLA-expressing antigen-presenting cell. The polymorphic determinants on the HLA molecule determine the binding and presentation of the antigenic peptide related to the target tissue, such as the joint. In model 3, T-cell specificity is directed toward the polymorphic amino acid residues of the HLA molecule itself by molecular mimicry. The immune response is postulated to focus on an HLA-positive target by virtue of cross-reaction with an antigen mimic that has successfully bypassed normal tolerance mechanisms and stimulated the reactive T cell. A variation of the mimicry hypothesis that partly reconciles all three models postulates that the polymorphic sequence on the HLA molecule is the primary antigenic target but that it is seen by the TCR as a processed self-peptide, bound and presented by another intact HLA molecule. (Major histocompatibility complex structural models for the figures in this chapter were constructed with molecular homology modeling techniques by Carol DeWeese, Department of Bioengineering, University of Washington School of Medicine.)

TABLE 89.2

Risk estimates for rheumatoid arthritis in white individuals

HLA class II allele	Frequency/10,000 population		Approximate risk ratio
	+RA	No RA	
DRB *0401	50	1800	1 in 35
DRB *0404	25	500	1 in 20
DRB *0101	25	2000	1 in 80
0401 or 0404	65	2300	1 in 35
0401, 0404 or 0101	90	4200	1 in 46
0401 and 0404	15	100	1 in 7
Other	10	5800	1 in 580

These numbers represent the “absolute risk” for the development of clinical rheumatoid arthritis in white individuals. They are based on a disease frequency of 7 to 10 per 1000 population and accordingly represent an upper limit of the predictive value.

Adopted with permission from Nepom G. Prediction of susceptibility to rheumatoid arthritis by HLA genotyping. *Rheum Dis Clin North Am* 1992;18:785-92.

are present throughout the life of a patient and therefore by definition before onset of the disease. As a consequence, susceptibility and severity are inextricably linked.

ROLE OF NON-MAJOR HISTOCOMPATIBILITY COMPLEX GENES

Calculations based on monozygotic twin concordance rates and HLA haplotype sharing in affected sibling pairs indicate that HLA genes contribute approximately 30% of the total genetic risk for RA.^{7,68} This leaves considerable room for other genes outside the HLA region to contribute to risk for RA. It is likely that the remaining genetic risk is distributed among many loci across the human genome, with each locus contributing substantially less than the HLA region to overall RA risk.⁶⁹

Genome-wide linkage scans in rheumatoid arthritis

The human genome is riddled with DNA variants (alleles) that make each of us unique. There are single-base pair variants (also known as SNPs) and structural variants (including duplications and deletions of many kilobases of DNA). These variants are further classified by the frequency with which they are observed in the general population. As a rule of thumb, variants present in more than 5% of chromosomes from the general population are considered “common,” and those present in less than 5% are considered “rare.” Rare variants can be further classified as “low frequency” (found in multiple families but generally with a population frequency of >0.5%) or “private” (segregating in only a single family as a result of a recent *de-novo* mutation).

A fundamental challenge in human genetics has been *how to systematically test human genetic variation to determine its role in human disease*. The ideal genetic study would resequence the entire human genome in a large collection of patients with a disease and controls in which detailed environmental exposure and clinical phenotypic information have been collected. Causal mutations would be recognized by a simple test of association between allele frequency in cases and controls while controlling for potential environmental and clinical confounders. Assuming complete coverage of the human genome, this hypothetical approach would identify all classes of DNA variants (e.g., SNPs, copy number variants) and the entire allele frequency spectrum (e.g., common and rare) in an unbiased manner. Such an approach, however, is impractical because of current limitations in technology and cost constraints.

Initial attempts to scan the human genome used hundreds of microsatellite markers and tests of “linkage” in families. These studies relied on meiotic recombination between a microsatellite marker and an unknown mutation that increases risk for disease. This approach has been very successful in identifying rare, highly penetrant alleles that predispose to mendelian forms of disease. However, this strategy has had limited success in patients with more complex patterns of inheritance, such as RA. Because of the theoretic limitations of linkage scans, researchers in the early 2000s turned their attention to genetic studies of “association.”

Candidate gene association studies in rheumatoid arthritis

An alternative statistical approach to genome-wide linkage was to conduct genome-wide genetic association studies. Instead of mapping disease genes by following transmission in families, association studies compare the frequencies of genetic variants among affected and unaffected individuals. Theoretically, association studies have more power than linkage studies to detect common variants of modest effect size.⁷⁰ Until recently, genetic association studies were limited to candidate genes. This was simply a matter of practicality because it was prohibitively expensive to genotype more than a handful of SNPs in large patient samples. Furthermore, no comprehensive map of common genetic variation was available, and it was unclear how many SNPs would need to be genotyped to test the majority of common human variations.

One solution in the early 2000s was to select biologically plausible candidate genes and test SNPs that were found in and around these genes. A major limitation of this approach was obvious: there are more than 20,000 genes in the human genome, and most candidate gene studies are limited to a small number of candidate genes. A handful of successes were achieved.

PTPN22

One candidate gene association study selected putative functional SNPs from a set of biologic candidate genes. With this approach, a missense SNP

in the intracellular *PTPN22* gene was identified.⁷¹ Outside the MHC region, this gene became the first to be widely replicated in multiple independent collections. The susceptibility allele is a missense variant in which an arginine is changed to tryptophan (R620W). The change results in altered binding of the *PTPN22* protein to an intracellular signaling molecule called Csk, which subsequently alters the threshold of T-cell activation.^{71,72} The magnitude of the genetic effect, as measured by the OR, is substantially less than that for HLA-DRB1*0401 but similar to other SE alleles (*PTPN22* OR ≈ 1.75). Interestingly, this allele is absent in east Asians and thus not associated with susceptibility in Japanese populations.⁷³ *PTPN22* associates only with seropositive RA. There is some evidence that *PTPN22* influences age at onset⁷⁴ and may have a more significant effect in males than in females^{74,75} but no evidence that it influences disease activity or radiographic erosions.^{76,77}

PADI4

PADI4 encodes an enzyme that posttranslationally changes arginine to citrulline and may therefore be important in generating anti-CCP autoantibodies. Based on this hypothesis, a Japanese group tested more than 100 SNPs in the region that contains *PADI4* and a cluster of related genes. In the initial report, a common variant (population allele frequency $\approx 35\%$) was found to increase risk for RA.⁷⁸ Subsequent reports provided support for this allele in individuals of Asian ancestry, with a meta-analysis showing an OR of 1.30 per copy of the risk allele.⁷⁹ The same allele is either not associated or only modestly associated (OR < 1.10) with risk for RA in individuals of European ancestry.^{74,79,80}

CTLA4

CTLA4 is a negative regulator of T-cell activation. Based on this biology, genetic studies in the early 2000s tested SNPs for association with several autoimmune phenotypes. The association between *CTLA4* and susceptibility to autoimmunity was initially confirmed in patients with type 1 diabetes and autoimmune thyroiditis.⁸¹ An allele in the 3' untranslated region of the gene causes a modest increase in risk for disease (OR = 1.2). Several studies extended these findings to RA, for which the magnitude of the genetic effect is reproducible but modest (OR = 1.15).^{74,82} The association is stronger in autoantibody-positive RA patients.

STAT4

Another strategy for choosing candidate genes is to select those that are biologically plausible *and* localized in suggestive regions of linkage. With this strategy, Remmers and colleagues⁸³ studied haplotype-tagging SNPs within 13 candidate genes under a linkage peak on chromosome 2. In a staged design of more than 7500 case-control samples, one SNP was reproducibly associated with risk for RA (OR = 1.20). This result has been replicated by others. *STAT4* plays a critical role in differentiation of T cells into distinct lineages. It is unclear whether the risk allele alters *STAT4* gene expression. There is no known coding variant that disrupts *STAT4* function.

Genome-wide association studies in rheumatoid arthritis

These four successes notwithstanding, the majority of candidate gene association studies have not led to reproducible genetic associations in RA.⁷⁴ Accordingly, a set of resources has been developed to systematically test the majority of common SNPs for their role in disease. The rationale for this approach is rooted in population genetic theory: common SNPs explain much of the genetic diversity in our species. This is a consequence of the historically small size and shared ancestry of the human population.

There are approximately 10 million common SNPs in the human genome, although 90% of these SNPs are highly correlated ($r^2 > 0.80$).^{84,85} As a consequence, not every SNP in the human genome needs to be tested directly in a genetic association study. A subset of “tagging” SNPs can adequately capture the majority of common genetic variations across a locus; this is also known as linkage disequilibrium (LD) mapping. The International Haplotype Map (HapMap) Project has provided a catalog of common SNPs in the human genome,^{84,85} which facilitates LD mapping. The HapMap has genotyped more than 3 million SNPs in four reference groups from a total of 270 individuals.

Genetic studies of common variants can now be conducted across the entire human genome. Such studies, termed genome-wide association studies (GWASs), are feasible because of improved understanding of LD structure across the human genome,^{84,85} technical capacity to genotype hundreds of thousands of SNPs in a cost-effective manner,⁸⁶ and methods of analyzing large data sets.^{87,88} GWASs have a distinct advantage over previous

genetic studies in that they are able to test, in an unbiased manner, the majority of common SNPs across the genome in a single experiment. Implementation of GWASs has greatly expanded the number of true-positive loci (i.e., those that have been replicated consistently in more than one study at a high level of statistical confidence) that are associated with complex traits.⁸⁹

In 2007, three GWASs of RA were published, and two new RA risk loci were identified.⁹⁰⁻⁹² One GWAS was a collaborative effort between groups in North America (NARAC) and Sweden (EIRA).⁹² A total of around 1500 anti-CCP+ RA patients and about 1800 controls were genotyped for more than 300,000 SNPs, followed by replication of the most significant SNPs in an additional approximately 1000 anti-CCP+ RA cases and about 1700 controls. The most significant result outside *PTPN22* and the MHC loci was the *TRAF1-C5* locus. A single SNP on chromosome 9 was strongly associated with susceptibility to anti-CCP+ RA (OR = 1.20). An independent group identified the same DNA variant as part of a candidate gene association study.⁹³

Two other GWASs led to identification of the *TNFAIP3* locus on chromosome 6q23.^{90,91,94} Interestingly, two independent risk alleles were identified, although both were within 5 kb of each other. Both alleles reside approximately 185 kb away from the nearest biologic candidate gene, *TNFAIP3*. The distance of the risk alleles from the nearest candidate gene underscores a limitation of candidate gene association studies: many risk alleles reside some distance from the protein-coding sequence. *TNFAIP3*, also known as A20, is a potent inhibitor of NF- κ B (nuclear factor κ -light chain enhancer of activated B cells) signaling and is required for termination of tumor necrosis factor- α (TNF- α)-induced signals.⁹⁵ TNF- α levels are increased in patients with RA, and inhibition of TNF- α is a potent treatment of severe RA.⁹⁶ Furthermore, mice lacking *Tnfaip3* demonstrate chronic inflammation,⁹⁷ consistent with loss of function of this gene playing a role in autoimmunity. Even though it may be logical to conclude that the RA risk alleles alter expression of *TNFAIP3*, no direct data support this claim. A variety of 6q23/*TNFAIP3* alleles, some of which are different from the RA risk alleles, contribute to risk for other autoimmune diseases.

Follow-up studies of these GWASs have identified more than 50 RA risk loci.⁹⁸⁻¹⁰⁰ Several important observations have emerged: (1) hundreds (if not thousands) of alleles contribute to risk for any given complex disease,^{101,102} (2) each allele has a small effect on risk, and (3) most alleles discovered to date are common in the general population (although this is a biased estimate because only common alleles have been tested by contemporary GWASs).

Other follow-up GWASs have capitalized on the observation that many RA risk loci are associated with other autoimmune diseases. As an example, epidemiologic data suggest an overlap among the risk factors for type 1 diabetes and RA.¹⁰³ Consistent with this observation, a locus on 4q27 containing the *IL2* and *IL21* genes demonstrates a clear association with risk for type 1 diabetes and a highly suggestive association with risk for RA.¹⁰⁴ Approximately half the validated RA risk loci have strong evidence of association for at least one additional autoimmune disease. Frequently, the same allele confers risk for both autoimmune diseases (e.g., 4q27/*IL2-IL21* and risk of RA/type 1 diabetes). In other instances, different alleles at the same locus confer risk for disease (e.g., *TNFAIP3* and risk for RA/psoriasis). Occasionally, the same allele confers risk for one disease and protection against another (e.g., *PTPN22* and risk for RA/protection against Crohn disease).¹⁰⁵

Although GWASs and related approaches have greatly expanded the number of RA risk loci, the non-MHC alleles that have been validated explain less than 5% of the disease variation.⁹⁸ The alleles identified to date are common and of modest effect size. Based on considerations of statistical power, many more RA common risk alleles will be identified in the near future. These discoveries will require continued international collaboration given the large sample sizes needed to achieve statistical significance.

Insight into the pathogenesis of rheumatoid arthritis from non-major histocompatibility complex genetic studies

Despite decades of research, the exact cause of RA is unknown.¹⁰⁶ Without knowing the specific pathways that lead to RA, it is very difficult to develop novel therapies and preventive strategies. Because genetic mutations are inherited before onset of disease, human genetics provides *prima facie* evidence that a pathway is important in pathogenesis. Moreover, because human genetics studies can be done without any specific biologic hypothesis (other than the hypothesis that there are alleles that influence risk for RA), human genetics offers an unbiased search of the human genome.

When considering pathways implicated by genetic studies, there are two important caveats in the way in which risk alleles are often described. First,

the risk locus is frequently assigned a gene name (e.g., *TNFAIP3*) even though there may be no direct evidence that the gene itself has been disrupted by the risk allele. Generally, the most compelling biologic candidate gene from a locus is chosen. Sometimes the choice is clear, as in the case of *TNFAIP3*, in which a knockout mouse model demonstrates severe inflammation, consistent with the phenotype of RA.⁹⁷ Second, the reported risk allele most likely represents a highly correlated proxy for the as-yet unidentified causal allele (i.e., the causal allele has not yet been identified). In other words, for most RA risk loci, the exact causal mutation and the exact causal gene have not yet been determined.

Despite these caveats, recent genetic discoveries have identified pathways that are important in RA pathogenesis. One is the NF- κ B signaling pathway.¹⁰⁷ NF- κ B, a protein complex that acts as a transcription factor, is found in almost all cell types and is involved in a variety of cellular responses to stimuli. Both TNF and CD40 signal through NF- κ B to exert their effects on the immune system. Several of the RA risk loci contain genes that are involved in NF- κ B signaling, including *CD40*, *TRAF1*, *TNFAIP3*, *PRKCQ*, and *TNFRSF14*.

Integration of GWAS data with gene expression and epigenetic data points to the critical role of certain cell types.^{108,109} GWASs implicate the importance of CD4+ T cells in risk for RA. As the list of GWAS hits expands, it is likely that additional pathways and cell types will be identified.

GENE AND ENVIRONMENT INTERACTIONS

With the heritability of RA being approximately 60%,¹⁰ the remainder of the variance in the disease must be accounted for by environmental, nongenetic factors or complex gene-gene/gene-environment interactions. It seems plausible that interactions occur between genetic and environmental factors or that environmental factors function as “triggers” for promoting and driving the disease process.

Smoking is the known environmental risk factor with strongest risk for development of RA. Over the past 20 years, many studies have convincingly shown that smoking increases the risk for RA in both males and females by a factor of approximately 1.5 to 2.0.^{110,111} Most of these studies demonstrate that the increased risk is for the development of autoantibody-positive RA and that the risk is greatest for heavy, current smokers. The risk remains, however, for longer than 10 years following smoking cessation.

Other putative environmental risk factors that have not been as widely replicated as smoking include blood transfusions, obesity, occupational silica and mineral oil exposure, and socioeconomic class.^{112,113} It is interesting that several of these putative environmental factors are inhaled through the lungs. Silica dust and mineral oil exposure, similar to exposure to cigarette smoke, was a risk factor only for seropositive RA. Mineral oil can also act as an adjuvant capable of inducing experimental arthritis in rodent models.

Even though smoking is a clear environmental risk factor and many MHC and non-MHC genes confer risk for RA, the question remains: is there an interaction between environmental and genetic risk factors that departs from an expected model? A challenge in the field is the definition of “expected model.” Given that most genetic risk factors conform to a multiplicative (or log-additive) model, the most conservative estimate is to define “interaction” as departure from a multiplicative model. The best example of a gene-environment interaction that appears to depart from a multiplicative model has been the interaction between cigarette smoking and HLA-DRB1 alleles. A study by Padyukov and colleagues¹¹⁴ using the Swedish EIRA cohort found evidence of an interaction between the presence of the SE and cigarette smoking. When compared with patients who had never smoked and had no copies of the SE, they found ORs of 2.8 in seropositive smokers with SE alleles who had never smoked, 2.4 in current smokers without SE alleles, and 7.5 in current smokers with SE alleles. Smokers carrying two SE alleles displayed an RR for rheumatoid factor-positive RA of 15.7. No influence of smoking or SE alleles was seen for seronegative RA. These data suggest an interaction between smoking, SE alleles, and seropositive RA.

Clearly, additional work is required to elucidate important interactions between genes and the environment. This will be an important area for future investigation and may empower the design of better clinical prediction models or novel gene discovery.

CONCLUSION

There is considerable evidence that genetic factors are important in the predisposition to RA and contribute to the heterogeneity of the broad

spectrum of disease that is currently classified as RA. The contribution of MHC genes and their interactions has yet to be fully elucidated, but recent work indicates that multiple genes within this region influence risk for disease. The SE hypothesis alone does not fully explain the complexity of the MHC contribution to RA, which has led to the refined “binding groove” model. Overall, the MHC contributes approximately a third of the total genetic contribution to RA. Advances in genetic technology have enabled unbiased scans of the human genome, and as a consequence, many non-MHC gene loci have been identified. Interactions between genes and environmental factors may be important, but work in this area is quite preliminary. Potential interactions between exposure to tobacco smoke and HLA and non-HLA genes are the best characterized to date. Clearly, much progress has been made, although substantial work is still needed to fully explain the genetic contribution to RA. Progress in this area is likely to translate into greater understanding of disease pathogenesis and the development of improved diagnostic and therapeutic tools for this chronic and disabling illness.

Animal models of arthritis

■ WIM B. VAN DEN BERG

- Arthritis may be induced in animals by immunization with cartilage components, by nonspecific immune stimuli, by bacterial or viral components, or by transgenic manipulation.
- Animal models are tools that mimic various aspects but never fully resemble human rheumatoid arthritis.
- Models have a defined onset and are useful for kinetic evaluation of arthritis, cell and mediator involvement, and detailed analysis of joint erosion.
- Animal models serve an important role in the evaluation of antirheumatic treatments and provide direction for novel approaches to treatment such as cytokine inhibition.

INTRODUCTION

Experimental animal models of arthritis have contributed to the understanding of basic mechanisms of joint disease. Marked diversity is seen among the numerous models, with arthritis being induced by the following:

- Immunization with cartilage components
- Injection of nonspecific immune stimuli
- Components of infectious agents
- Immune complexes
- Manipulation of genetic information in transgenic animals

No single animal model of arthritis truly represents the human disease. The wide variety of agents that can induce experimental arthritis with clinical and histopathologic features close to those of human arthritides suggests that disparate etiologic pathways could exist for rheumatoid arthritis (RA). Aspects peculiar to individual models are of value but must be interpreted with caution. Much can be learned from the general validity of mediator involvement and common concepts. Models provide valuable preclinical data for the development of novel treatments, both pharmacologic and biologic, and insight into relevant mechanisms common to both experimental arthritis and RA.

MECHANISMS OF INDUCTION OF EXPERIMENTAL ARTHRITIS

Autoimmunity to cartilage components

Articular cartilage is an intriguing tissue. It is the target of the disease, but it may also function as the trigger by releasing potential autoantigens and trapping exogenous antigens in its avascular matrix. Destructive forms of RA tend to decline when cartilage is fully destroyed, and arthritis also wanes in joints undergoing replacement surgery, both arguments for a crucial role of cartilage in the arthritic process. Classic arthritis models based on cartilage autoimmunity¹ can be induced by immunization with either of the two major components of hyaline cartilage: type II collagen (CII) and aggrecan proteoglycans (PGs). More recently, similar models have been developed in which other, less abundant cartilage components have been identified as potential autoantigens in arthritis.

In principle, any cartilage matrix component can potentially be arthritogenic, provided that it is released in substantial amounts and natural

tolerance is lost. Collagen-induced arthritis (CIA) can be elicited in mice, rats, and primates,^{2,3} whereas PG arthritis has been successfully established only in BALB/c mice.⁴ Both models require induction of a vigorous immune response directed initially against the immunizing (heterologous) cartilage antigen, which subsequently reacts with autologous cartilage antigens. A hypothetical mechanism for the development of CII- and PG-induced experimental arthritides is shown in [Figure 90.1](#).

Susceptible strains of animals immunized with either CII or high-density aggrecan PGs in adjuvant recognize specific epitopes. Autoreactive CD4⁺ T cells respond to either cross-reactive or cryptic epitopes (privileged antigens normally concealed from immune surveillance) and elicit connective tissue antigen-specific Th1 (type 1 helper T cell) and Th17 cells and autoantibodies. Adoptive and passive transfer experiments suggest that both immunologic elements are required for the generation of chronic arthritis, although transient but destructive forms can be elicited with cocktails of anti-CII autoantibodies only. Localization of antibody and reactive cells in synovial joints causes immune-mediated cartilage damage, and the immune response may be perpetuated by the release of cartilage antigens. These damage-associated molecular patterns may also directly activate cells through Toll-like receptors (TLRs), in particular, TLR4.

The pathology of CIA and PG arthritis appears to be similar and includes synovial hypertrophy and hyperplasia, which give rise to pannus formation and severe cartilage erosion. Both models were considered to be driven by Th1 cells, yet interferon- γ (IFN- γ) deficiency makes BALB/c mice more susceptible to CIA but it prevents PG arthritis. More recent insight has indicated a dominant role of Th17 cells in CIA, whereas Th1 cells are crucial in PG arthritis, and a role of Th17 in this model is unmasked only under IFN- γ -deficient conditions. Neutralization of tumor necrosis factor (TNF) was efficacious in early stages of CIA, and interleukin-1 (IL-1) blocking and IL-17 neutralization suppressed both early and fully established arthritis.⁵

Response to nonspecific immunologic stimuli

Injection of nonspecific agents with adjuvant activity (the capacity to elicit an indirect immunologic response) can provoke experimental arthritis in certain species. The classic example is adjuvant-induced arthritis (AA) in the Lewis rat.⁶ The precise contributions of the oil and the mycobacterial components of Freund complete adjuvant in the pathologic pathway of this experimental disease remain unclear, but both may contribute. A bacterium-specific pathogenesis seems likely in AA because conventionally bred rats are generally resistant to AA whereas germfree Fisher or Wistar rats are susceptible. Germfree rats lack early contact with bacteria and therefore tolerization does not occur. This is in striking contrast to suppression of pristane (mineral oil)-induced arthritis in germfree mice, hence implying a different pathogenesis.

Adjuvant- and pristane-induced arthritis

Incomplete Freund adjuvant, which lacks mycobacteria, and the mineral oil pristane, can induce arthritis in susceptible rats and mice, evidence that oil can override natural tolerance.⁷ The arthritogenic consequences appear to ultimately depend on a reaction against either exogenous or autologous antigens. Heat shock proteins may be regulators in AA.⁸ A hypothetical mechanism for the development of AA and pristane-induced arthritis is shown in [Figure 90.2](#). In susceptible strains of animals, macrophages phagocytose nondegradable oil components, become intensely activated, and produce large concentrations of proinflammatory cytokines (IL-1, IL-6, TNF, and IFN- γ). This cytokine-rich environment activates T and B cells. The results of polyclonal activation are apparent in pristane-induced arthritis, in which lymphadenopathy and hypergammaglobulinemia precede the onset of disease.

HYPOTHETICAL MECHANISM FOR THE DEVELOPMENT OF COLLAGEN-INDUCED AND PROTEOGLYCAN-INDUCED EXPERIMENTAL ARTHRITIS

Fig. 90.1 Animals are immunized with type II collagen or high-density aggrecan proteoglycans, and an autoimmune response results when specific epitopes are presented in the context of major histocompatibility complex (MHC) class II antigens and recognized by autoreactive CD4+ T-cell populations. Autoantibodies and T effector cells reactive against cartilage components develop via helper T-cell pathways (Th1, Th17, and Th2) and localize in synovial joints, which causes an immune-mediated inflammatory response. The immune response is perpetuated by the release of cartilage antigens within the damaged joint, and chronic arthritis develops.

HYPOTHETICAL MECHANISM FOR THE DEVELOPMENT OF PRISTANE-INDUCED AND ADJUVANT-INDUCED EXPERIMENTAL ARTHRITIS

Fig. 90.2 Circulating macrophages become intensely activated by the nondegradable oil components and produce high levels of proinflammatory cytokines (interleukin-1 and interleukin-6, tumor necrosis factor- α , and interferon- α). Genetic regulation governs the presence of autoreactive T cells and B cells, which become activated and clonally expand. Joint-reactive lymphocytes migrate to the joint and induce immune-mediated joint damage. The release of cartilage antigens and heat shock proteins may feed back to the autoreactive lymphocytes and result in chronic immune stimulation. Cytokines may also act directly on both synovial cells and chondrocytes and thereby result in synovial hypertrophy, abnormal expression of major histocompatibility complex (MHC) class II antigens and adhesion molecules, and atypical production of matrix components. Arthritis develops as a result of the chronic nature of the inflammatory stimulation.

Expansion of autoreactive T- and B-cell populations can occur as a consequence of the adjuvant activation process and result in the migration of cells to the joint and subsequent immune-mediated joint damage and production of a spectrum of autoantibodies against cartilage antigens. Disease onset is rapid in AA (2 weeks), often followed by spontaneous remission. Pristane-induced arthritis is slower (months) and characterized by remissions and relapses, with no indication of B-cell involvement at the onset. The pristane model is highly suited to studying genes controlling onset, severity, and chronicity.⁹ The spontaneous remission and lack of

susceptibility to reinduction make AA a suitable model for studies on the regulation of T-cell tolerance. Histopathologic study of AA shows major involvement of bone marrow, bone erosion, extensive bone apposition, and minor direct cartilage damage in the early stages (Table 90.1).^{2-4,6,7,10-24} Indirect cartilage damage occurs later, mainly as a consequence of the loss of underlying bone. The latter may explain the cartilage-protective effect of treatment with osteoprotegerin (OPG), which is a selective inhibitor of the osteoclast activator RANKL (receptor activator of nuclear factor κ B ligand).^{10,25} Combined blocking of TNF and IL-1 is associated with optimal control of arthritis and joint destruction.

Components of infectious agents

The development of arthritis as a consequence of infection is apparent in both natural and induced animal models. Infectious agents may be tropic for the joint as a result of expression of adhesins or other molecules that promote sequestration within synovial tissue. Bacterial cell wall and *Mycoplasma* membrane components may also provide nonspecific immune activation through mitogenic activity. Viral infection of synovial cells may elicit novel cell-surface antigens or abnormal expression of activation antigens and the overproduction of autoantigens. Viral infection may also disrupt immune regulation and increase proinflammatory cytokines and immune activity against normally immunologically privileged components of the joint.

Streptococcal cell wall arthritis

Persistence of antigens from microorganisms within the joint can be critical for the induction of arthritis (Fig. 90.3). Streptococcal cell wall (SCW) arthritis can be induced in Lewis rats¹¹ by the systemic injection of cell wall fragments of group A streptococci, which are highly resistant to biodegradation. A similar disease can be induced with fragments from other bacteria, such as *Lactobacillus casei* or *Eubacterium aerofaciens*. The underlying principle of this model resides in the poor degradability of the fragments, thereby creating a persistent stimulus.

The *Lactobacillus* and *Eubacterium* models are of particular interest for human disease because these bacteria are part of the normal gastrointestinal flora. An enormous load of potential arthritogenic stimuli is continuously present in the normal gastrointestinal tract, fragments may spread in a noninfectious manner to other tissues, and this may provoke arthritis when immunoregulatory control is insufficient.

Within 24 hours of administration of cell wall fragments to rats, acute inflammation develops in peripheral joints, coincident with dissemination of the cell wall fragments in blood vessels of the synovium and subchondral bone marrow. The acute, complement-dependent inflammation subsides over the next week, followed within 2 weeks by a chronic, T cell-dependent erosive polyarthritis involving mainly peripheral joints. Chronic joint inflammation develops only in susceptible strains that are unable to maintain tolerance and therefore display SCW-specific T-cell responses. Lewis rats are highly vulnerable to this arthritis. The mouse strains studied thus far are not susceptible to the single intraperitoneal injection model, and repeated dosing is needed to break tolerance. It is tempting to speculate that similar loss of tolerance may occur in RA patients with age, combined with costimulatory environmental factors.

Fig. 90.3 Infection of macrophages and monocytes induces both expression of cell-surface viral antigens and release of cytokines. Macrophage activation appears to promote both CD4+ type 2 helper T-cell (Th2) expansion and the development of activated CD8+ T cells. T-cell cytotoxicity directed against infected type A (macrophage lineage) synovial cells may result in a local inflammatory reaction within the joint, and cartilage may be damaged concomitantly. The increased Th2 activity may contribute to local immune complex formation, which eventually leads to chronic inflammatory activity within the joint and the development of arthritis.

Studies of the involvement of cytokines in SCW arthritis show a combined role of TNF and IL-1, as found in AA.¹² In mice, a chronic relapsing SCW model can be induced by repeated weekly injection of SCW fragments directly into the knee joint, which displays a gradually increasing role of T cell–derived IL-17 and synovial IL-17 receptor-bearing cells with every flare.²⁶

Bacterial DNA can induce arthritis. In particular, the CpG motifs are arthritogenic and substantial amounts can be found in joint tissues.²⁷ Macrophages play a major role in this arthritis through TNF production. However, in comparison to cell wall fragments, the cytokine-inducing capacity of bacterial DNA is weak. Normal joints of individuals contain both bacterial fragments and bacterial CpG (CP61) motifs, and it is conceivable that both factors contribute to arthritis.

Antigen-induced arthritis

Antigen-induced arthritis (AIA) provides a designed model of the development of chronic erosive arthritis that reflects a sustained immune reaction to a persistent trigger in joint tissues, in this case a planted protein antigen. It is elicited by local injection of a high dose of antigen into the knee joint of an animal previously hyperimmunized with that antigen in Freund complete adjuvant. Such a model was first developed by Dumonde and Glynn¹³ in rabbits. In principle, it can be induced in any species, provided that proper immunity to a particular antigen can be mounted. Applications have since been developed in mice, rats, and guinea pigs.

In contrast to the polyarthritis models described thus far, AIA remains confined to the injected joint. Commonly used antigens are ovalbumin, bovine serum albumin (BSA), fibrin, and cationic forms such as methylated BSA. Preimmunization with antigen in complete Freund adjuvant induces strong humoral and cell-mediated immunity. Arthritis is usually induced 3 weeks later by local injection of a large amount of antigen into the knee joint. Initially, an immune complex (IC) type of reaction dominates, followed by T cell–mediated chronic inflammation. In the rabbit, chronicity may last for years. Histopathologic examination shows a granulocyte-rich exudate in the joint space, thickening of the synovial lining layer, and at later stages, a predominantly mononuclear infiltrate in the synovium, which later includes numerous T cells and clusters of plasma cells making antibodies to the inciting antigen, thus implying that retained antigen is still a driving force in chronic arthritis. Intense IC formation is seen in superficial layers of the articular cartilage, which may contribute to localized cartilage destruction. Early loss of PG, followed by pannus formation and cartilage and bone erosion, is a common finding.

Two important principles emerge from this model: first, chronicity occurs only in the presence of sufficient antigen retention in joint tissues, in combination with proper T cell–mediated delayed hypersensitivity; and second, joints contain numerous noncollagenous and avascular collagenous tissue such as cartilage, ligaments, and tendons, which allows prolonged antigen retention by antibody-mediated trapping and charge-mediated binding.^{14,28} Chronicity is caused by the generation of local antigen-specific T-cell hyper-reactivity, which allows flares in response to tiny amounts of antigen.

In rabbits, antibody responses are generally high and allow sufficient IC-mediated trapping of antigen in the joint. Because antibody levels are lower in mice, cationic antigens are needed as suitable arthritogens because of their ability to stick to the negatively charged collagenous structures of the joint and to accumulate IC formation at the surface.²⁸ Of interest, this principle may extend to cationic bacterial or viral components and appears to be of importance in the more recently developed KRN model of arthritis, in which anti-glucose-6-phosphate isomerase (anti-GPI) antibodies stick to GPI antigen trapped at cartilage surfaces.

In AIA in the rabbit and the mouse, elimination of TNF and IL-1 was poorly effective in suppressing joint inflammation, thus pointing to substantial “overkill” by other mediators in this severe onset of arthritis. However, elimination of IL-1 did yield impressive protection against cartilage destruction. The AIA model is most suited to studies of the mechanism of cartilage destruction as induced by a mix of ICs and T-cell reactivity. It is assisted by knowledge of the exact time of onset, accessibility of the knee joint (as compared with the ankles), and the presence of a contralateral control joint. Moreover, the model can be used to evaluate the regulation of local T-cell hyperreactivity against a retained foreign antigen.

Flares of arthritis

In contrast to the chronicity of human RA, most animal models have a relatively short duration of severe and rapidly destructive inflammation. In this respect, models of repeated flares of arthritis, with slower development of lesions, provide a valuable extension.

An arthritic joint bearing retained antigen and a chronic antigen-specific T-cell infiltrate displays a state of local hyperreactivity. This situation is not restricted to retained antigen but also applies to new antigen entering the sensitized joint from the circulation. Flares of smoldering arthritis can be induced with as little as 10 ng of antigen, and T cell–derived IL-17 plays a dominant part in such exacerbations.¹⁵

Similar flare models have been developed in rats and mice with bacterial cell wall constituents. Bacterial fragments may function as an antigen but also directly trigger TLRs, in particular, TLR2. The ensuing reactions are a mixture of T cell– and macrophage/fibroblast-driven processes. In the mouse model of repeated SCW rechallenge, the swelling response of every flare remains dependent on TNF. However, the chronic erosive infiltrate in the synovial tissue that occurs after repeated challenges is dependent on IL-1. Cartilage erosion is absent in IL-1–deficient mice but does occur in TNF-deficient mice. This model is more severe and erosive in DBA mice than in C57Bl mice, erosion is absent in T/B cell–deficient RAG–/– mice, and blocking of IL-17 prevents an erosive phenotype. The repeated-challenge model becomes Th17 dependent, and IL-1 is a major cytokine driving this process of Th17 generation.²⁶

Of note, considerable cross-reactivity occurs between cell walls from different bacterial origins, and flares may result from homologous and heterologous fragments. This may extend to cross-reactive autoantigens from cartilage, which underlines the fact that arthritis can start in response to a particular antigen but may spread to other antigens, including autoantigens.

Recently, TLRs have been identified as recognition sites for bacteria. TLR2 is involved in SCW recognition, whereas TLR4 is triggered by lipopolysaccharide but also by the damaged connective tissue components released in erosive stages. The acute SWC arthritis model is dependent on TLR2, whereas the more chronic rechallenge model loses TLR2 dependence and becomes dependent on TLR4.²⁹ These principles open up a wide range of putative stimuli involved in exacerbations, which simultaneously complicates the search for the driving “antigen” in humans. Flares can be blocked efficiently with a combination of antibodies to TNF, IL-1, and IL-17¹⁵ in particular. Evaluation of the efficacy of TLR blockers is warranted.

Immune complex–induced arthritis

Autoantibodies such as rheumatoid factor and anti-citrullinated peptide antibodies (ACPAs) are a key feature of RA, and the recent success of treatment with an anti-B cell drug (rituximab) enhanced the interest in their pathogenic role. In some of the models discussed earlier such as collagen-

PG-, and antigen-induced arthritis, IC formation at joint tissues is a major element (see Table 90.1). Although excessive IC formation can cause destructive arthritis, chronicity is limited and much promoted by T cells.³⁰ Minute amounts of antigen suffice to stimulate T cells, whereas considerable amounts of ICs are necessary to stimulate the release of inflammatory mediators from phagocytes. It is likely that IC models mimic part of the RA pathology.

Interest is growing in the use of passive IC models, along with the availability of a range of transgenic knockouts, to identify crucial pathways of inflammation and tissue destruction. The advantage of passive systems is the lower dependence on genetic background, thereby avoiding excessive backcrossing to create transgenics in suitable, susceptible mouse strains. Passive transfer of collagen-induced arthritis can be performed with a critical mixture of a number of anti-CII monoclonal antibodies, including complement-binding IgG2a. Sets are now commercially available, with DBA mice routinely recommended as sensitive recipients. Accepted concepts of inflammation pathways include IC-mediated complement activation and Fcγ receptor triggering on phagocytes.

An IC model emerging from the murine AIA model and using the principle of cationic retention is the passive transfer of antilysozyme antibodies to mice by local injection of poly-L-lysine (PLL)-coupled lysozyme into one knee joint. PLL-coupled lysozyme is highly cationic and sufficiently large to be retained in the joint for prolonged periods. Both association with synovial tissue and heavy sticking to cartilage surfaces contribute to the chronicity and cartilage destruction. An intriguing observation is the more chronic and destructive nature of this arthritis in DBA/1j mice than in BALB/c mice,³¹ which seems to be related to high sustained levels of activating Fcγ receptors on the macrophages of DBA/1j mice. The model shows strong dependence on IL-1, whereas TNF blockade was ineffective. FcγRI rather than FcγRIII appears to be crucial in the cartilage damage.³²

A final model to be mentioned here is the passive GPI model, which is addressed following a description of KRN arthritis. Differences between the various IC models lie mainly in the subclasses of antibodies and related complement-binding activity or FcγR-mediated activation of granulocytes, macrophages, and mast cells.

KRN–glucose-6-phosphate isomerase arthritis

An intriguing, novel arthritis model emerged from experiments in transgenic mice overexpressing a self-reactive T-cell receptor (TCR). Arthritis developed in a cross of K/BxN mice.¹⁶ The beauty of the KRN model is elucidation of the driving antigen and identification that passive transfer with antibodies induces a protracted arthritis. The TCR recognized the ubiquitous self-antigen GPI and provoked, through B-cell differentiation and proliferation, high levels of anti-GPI antibodies. These antibodies are directly pathogenic on transfer and appear to recognize endogenous GPI, which seems to associate preferentially with the cartilage surface.³³ The latter may underlie the dominance of joint pathology in these mice, although GPI is also abundant in other sites in the body. IgG1 antibodies are the major subclass and cause a sustained, erosive arthritis after continued transfer, with high sensitivity in BALB/c mice. This pathology brings the model close to passive CIA or IC-induced arthritis with planted cartilage-associated antigen, all having IC formation at the cartilage surface. Differences relate to the IgG subclasses involved.

As an adaptation of this model, Kamradt and colleagues³⁴ immunized mice with GPI and showed the development of arthritis after a few weeks. This direct immunization model is a mix of GPI-specific T cells and anti-GPI antibodies; serum from these mice cannot transfer arthritis. The latter makes the direct immunization model different from classic KRN arthritis.

Strain and cytokine dependency of passive immune complex arthritis

The severity of arthritis is dependent on complement factors and Fcγ receptors. Activation of complement through the alternative pathway appears to be crucial in GPI arthritis, consistent with dominance of IgG1. The activity of complement and the level of expression of FcγR on phagocytes are different in various mouse strains, and this determines to a great extent the variable susceptibility. BALB/c mice are hyperreactive, whereas DBA/1 and C57Bl6 are less susceptible, and minor responsiveness is seen in 129/Sv mice, in strong contrast to the low sensitivity of BALB/c mice in other passive IC arthritis models. GPI antibodies are found in some RA patients but certainly not in all, and levels are moderate. Their role in RA remains to be identified.³⁵

IL-1 is obligatory, with no arthritis induced in IL-1–deficient mice. TNF is also essential, although less critically so than IL-1 because robust arthritis develops in a proportion of TNF-deficient mice. When compared with the passive arthritis induced with antibodies to the cationic antigen

PLL-lysozyme, higher TNF sensitivity is apparent, as well as a dependence on mast cells. These findings suggest a role of environmental initiating elements. It is likely that the onset of mild GPI arthritis is assisted by local TNF generation and mast cell-dependent release of histamine, whereas a model with a planted cationic antigen in the joint generates sufficient non-specific inflammation to initiate arthritis without the need for additional facilitating mediators such as TNF. Once affected, the role of TNF is limited, as in GPI arthritis. T cell-derived IL-17 can accelerate and enhance the expression of GPI arthritis,³⁶ thus making TNF redundant and illustrating the remarkable potency of the combination of IC and T-cell activation in the severity and chronicity of arthritis.

Citrulline-induced arthritis

ACPAs are a key feature of RA, and in recent years many researchers have attempted to prove the efficacy of such antibodies in RA patients to induce passive arthritis, thus far without much success. So the question remained whether the antibodies are pathogenic or just a marker of RA.³⁷ There is some suggestive evidence of a pathogenic role in the studies of Kuhn and colleagues,³⁸ which demonstrated that such antibodies are present in collagen-induced arthritis and that tolerization of mice to citrulline responses results in reduced arthritis. However, it cannot be excluded that the immunomodulation process caused innocent bystander effects, not necessarily solely reflecting suppressed anticitrulline responses.

Very recently, Holmdahl's group generated a range of monoclonal antibodies specific for citrullinated CII and demonstrated induction of arthritis on transfer of the antibodies. In addition, the antibodies could amplify smoldering arthritis.³⁹ This argues that defined anticitrulline antibodies can do the job, as was demonstrated earlier for anti-CII and anti-GPI antibodies. Whether similar antibodies occur in significant quantities in patients with RA remains to be proved.

Gene manipulation and transgenic models

Transgenic animals provide models that demonstrate the importance of certain principles in arthritis and are useful for distinct screening. They do not necessarily provide better translational models for drug targeting in RA.

In mice transgenic for the env-pX region of the human T-cell leukemia virus type 1 genome, a spontaneous chronic arthritis develops as a result of expression of the *tax* gene.²² Onset occurs at 2 to 3 months of age in female mice but is delayed several months in male animals. The ankle joints are most frequently affected, and pannus formation leading to severe erosion of cartilage and bone is observed in the transgenic mice after several months of disease. The mice produce autoantibodies, and collagen immunization can provoke the onset or exacerbation of arthritis. It is tempting to speculate that a retrovirus could be involved in the pathogenesis of RA, possibly by influencing T-cell responses to cartilage antigens.

Another example is the occurrence of chronic autoimmune arthritis in mice with a point mutation in the gene encoding ZAP-70, a key signal transduction molecule in T cells.²³ The aberrant TCR function leads to positive selection of otherwise negatively selected autoimmune T cells. It is of great interest that in these mice disease fails to develop under microbially clean conditions despite active production of arthritogenic autoimmune cells. A single injection of zymosan provokes arthritis in a Dectin-1-dependent but TLR-independent manner.

Mice with a homozygous mutation in the gp130 IL-6 receptor subunit show enhanced signal transduction and STAT3 activation, and a lymphocyte-mediated RA-like joint disease develops. The increased proliferation of CD4+ T cells is due to elevated production of T cell-activating IL-7 by nonhematopoietic cells.²⁴

Tumor necrosis factor transgenic arthritis

In an elegant series of experiments, Keffer and coworkers¹⁷ provided insight into the role of TNF in induction of arthritis. By the introduction into mice of a modified human TNF transgene lacking a TNF 3' untranslated region involved in translational repression of TNF, it was shown that pronounced TNF overexpression results in chronic polyarthritis with a 100% incidence. Hyperplasia of the synovium, inflammatory infiltrates in the joint space, pannus formation, and cartilage and bone destruction were observed. Intriguingly, a similar form of arthritis also developed in targeted mutant mice lacking the 3' AU-rich elements, thus confirming the role of these elements in maintenance of a physiologic TNF response in the joint.¹⁸ A proposed mechanism is the inability of natural antiinflammatory signals, such as IL-10, to suppress TNF production under these conditions. These exciting findings stimulated a major search for functional mutations in TNF production in RA patients. However, no clear indications have been found so far.

This model is of great interest in identifying pathways of TNF-induced arthritis and screening the efficacy of various TNF-directed therapies. It is not surprising that anti-TNF treatment blocks the pathology, but it is a remarkable observation that some of the pathology runs through IL-1. Crosses of TNF transgenic mice with IL-1-deficient mice identified that inflammation is mediated by TNF. Bone erosion is 50% dependent on IL-1, whereas cartilage erosion is a fully IL-1-dependent process.⁴⁰ The model does not need T or B cells because arthritis occurs in TNF transgenic mice backcrossed to RAG-/- mice, and the pathology can be transferred with selected TNF-producing fibroblasts. The p55 type 1 receptor mediates TNF pathology, whereas the p75 type 2 receptor mediates suppression. Selective blocking of TNFR1, with the antiinflammatory effects of TNFR2 left unaltered, markedly reduced bone erosion.⁴¹ These observations provide a rationale for future treatment of RA with selective anti-TNFR instead of anti-TNF antibodies.

Interleukin-1 transgenic mice and interleukin-1 receptor antagonist-deficient mice

Transgenic IL-1 α overexpression induces chronic, destructive arthritis.¹⁹ Transgenic mice expressing human IL-1 α had high serum levels of IL-1, and a severe polyarthritis developed by 4 weeks of age. Hyperplasia of the synovial lining, pannus formation, and ultimately, cartilage destruction were evident. T and B cells were scant, but active granulocytes were abundant.

The opposite approach, elimination of IL-1 control by gene targeting of the endogenous IL-1 receptor antagonist (IL-1ra), also yielded a model of arthritis. IL-1ra deficiency in a BALB/c background resulted in pronounced arthritis at the age of 8 weeks.²⁰ Marked synovial and periarticular inflammation with invasion of granulation tissue and articular erosion was noted. Moreover, elevated levels of antibodies against immunoglobulins, CII, and double-stranded DNA were found, suggestive of autoimmune responses. Overexpression of a range of cytokines, including IL-1 β , TNF and IL-6, was observed in the joints before the onset of arthritis. Interestingly, autoantibody levels did not correlate with disease severity, which may imply that it reflects a reaction to damaged joint tissue.

In sharp contrast to the TNF transgenic model, the arthritis in IL-1ra-/- mice is strongly dependent on T cells, in line with the remarkable genetic restriction. It is consistent with the view that IL-1 is a crucial regulator of T-cell function. Undisturbed IL-1 action, in the absence of IL-1ra, apparently permits activation of IL-17-producing T cells directed against exogenous triggers or endogenous autoantigens. The spontaneous arthritis in IL-1ra-/- mice does not develop in germfree conditions and is reduced in TLR4-deficient mice.⁴² Likewise, KRN arthritis is dependent on gut flora.⁴³ TLR4 blockers are effective in the IL-1ra model.⁴⁴ Both TNF and IL-17 deficiency prevent the onset of arthritis.²¹ Features are highlighted in Table 90.2.

CYTOKINES AS TARGETS IN SUSCEPTIBILITY AND DESTRUCTION

Findings on TNF, IL-1, and IL-17 involvement have been addressed partly under the headings of the various models and are further summarized in Table 90.3.

TNF is a major mediator in the early stages of joint inflammation in every model. Although IL-1 is not a dominant inflammatory cytokine in all models, it is certainly the pivotal cytokine in the inhibition of chondrocyte PG synthesis in all models studied thus far, and blocking of IL-1 has a great beneficial impact on net cartilage destruction.⁴⁵ In line with this, chronic destructive arthritis could not be induced in IL-1-deficient mice in any of the classic arthritis models. In contrast, TNF deficiency reduced the incidence of autoimmune arthritis, but once joints became afflicted, full progression to erosive arthritis did occur.⁴⁶ It is unclear why IL-1 is such a dominant target in IC- and T cell-driven models whereas a crucial role of IL-1 in autoimmune RA is evident only in joint erosion and a role in RA joint inflammation is unlikely.

The novel T-cell cytokine IL-17 provides an additional target apart from TNF and IL-1. Local overexpression showed that it can accelerate the inflammation and tissue destruction in CIA, independent of IL-1, and IL-17 blocking appeared to be superior in the T-cell flare of AIA.¹⁵ Studies of human RA synovium in mice with severe combined immunodeficiency suggest that anti-IL-17 therapy is probably effective only in subgroups of RA with a clear T-cell signature.⁴⁷

Cartilage and bone destruction

Animal models are excellent tools for characterizing the kinetics of destructive pathways. The cartilage damage observed in different models ranges from a selective loss of cartilage underneath pannus tissue to overall loss of

matrix, starting with release of PG and, later, collagen damage. Killing of chondrocytes and complete loss of the superficial and middle cartilage layers are noted in severe forms. This underlines the fact that arthritic processes can be more or less destructive, depending on the underlying process and cytokine mixture. Enhanced degradation of matrix and inhibited synthesis of PGs by chondrocytes are general findings in all models. Aggressive overall cartilage loss is predominantly noted in the presence of IC deposition, whereas milder, more gradual forms of damage are noted in models driven by macrophage, fibroblast, or T-cell activation. Large variations in progressive destruction are also found in populations of patients with RA, which may imply separate pathogenetic pathways.

Chronic, irreversible destruction can take place under conditions that will hardly be considered inflammatory, and the opposite occurs as well. Symptomatic relief with antiinflammatory therapy is promising, but the main challenge of interrupting joint destruction remains. As an example, local IL-4 gene transfer did not suppress local inflammation yet markedly reduced the cartilage and bone destruction in CIA.⁴⁸ Crucial enzymes involved in loss of PG in cartilage were identified. Studies in ADAMTS4 and ADAMTS5 knockout mice showed that ADAMTS5 is the crucial enzyme in the PG loss in AIA and that its absence prevents not only PG depletion but also collagen damage. Accordingly, it opens a novel, indirect way for targeted treatment of cartilage erosion.⁴⁹

RANKL is the crucial activating cytokine of the bone-resorbing osteoclasts. In the absence of RANKL, joint inflammation continues in the passive GPI IC model of arthritis, but bone erosion is prevented. Similarly, when

TNF transgenic mice were crossed with c-fos-deficient mice, joint inflammation continued yet bone erosion was fully absent. C-fos mice lack functional osteoclasts. TNF-driven bone erosion is dependent on osteoclasts, and absence of osteoclasts alters TNF-mediated arthritis from a destructive to a nondestructive phenotype. In line with this, treatment with OPG, which is the natural inhibitor of RANKL, does not reduce inflammation in AA and TNF transgenic mice, yet bone erosion is reduced.⁵⁰ Recently, a direct role of autoantibodies to citrullinated vimentin was identified in the activation of vimentin-expressing osteoclasts.⁵¹

Further improvement of therapy and even bone repair can be achieved by combined blocking of cytokines and RANKL, as well as by providing an additional anabolic stimulus such as parathyroid hormone.⁵² These studies indicate that repair of bone is achievable, in line with the bone recovery noted in well-treated RA patients. Repair of cartilage remains a major challenge that probably requires tissue-engineering approaches with stem cells, biodegradable matrices, and supplies of crucial growth factors. A final remark on bone erosion versus bone apposition is in order. Unlike the situation in patients with RA, many arthritis models exhibit not only bone erosion but also pronounced new bone formation. These phenomena occur at distinct sites of the joint. The latter process, bone apposition, is virtually absent in TNF transgenic mice, and a TNF-inducible regulator of bone apposition, DKK-1, was recently identified.⁵³ It might be argued that most murine arthritis models are relatively devoid of TNF when compared with TNF transgenic mice and human RA, herein providing a possible explanation for the excessive bone apposition. Further studies are warranted on

factors that regulate the impact of osteoclasts and osteoblasts on bone metabolism under inflammatory conditions and its dependence on the local cytokine milieu, including old and novel players such as DKKs, transforming growth factor- β , bone morphogenetic proteins, and members of the Wnt family. Proper identification of their involvement and targeting in models may provide new ways of treatment.

- Further insight on the relevance of findings on erosive processes in animal models to human RA are hampered by the paucity of information on progression of cartilage erosion in patients with RA. Radiographs are a proper tool to evaluate progression of bone erosion, but the joint space narrowing identified with this technique is a nonsensitive measure and overlooks focal erosions occurring in cartilage. It is recommended that upcoming clinical trials of RA pay attention to

advanced imaging technologies to monitor changes in cartilage damage, which have yet to be explored and validated in animal models of arthritis.

- Arthritis may be induced in animals by immunization with cartilage components, nonspecific immune stimuli, bacterial or viral components, or transgenic manipulation.
- Animal models are tools that mimic various aspects but never fully resemble human RA.
- Models have a defined onset and are useful for kinetic evaluation of arthritis, cell and mediator involvement, and detailed analysis of joint erosion.
- Animal models serve an important role in the evaluation of antirheumatic treatments and provide direction for novel approaches to treatments such as cytokine inhibition.

Autoantibodies in rheumatoid arthritis

■ MARKUS HOFFMANN ■ KARIN LUNDBERG ■ GÜNTER STEINER

- Rheumatoid arthritis (RA) is a systemic autoimmune disease characterized by the presence of autoantibodies in peripheral blood and synovial fluid. Most autoantibodies are not directed to joint-specific antigens.
- Autoantibodies are already present in the earliest stages of the disease and may precede onset of the disease by several years.
- Rheumatoid factors (RFs), or autoantibodies to the Fc portion of IgG, are the longest-known marker antibodies in RA. High-titer IgM-RF and also IgA-RF are of high diagnostic and prognostic value because they are associated with erosive and more severe disease.
- Anti-citrullinated protein/peptide antibodies (ACPAs) are directed to antigens containing the unusual amino acid citrulline. They are the most specific marker antibodies for RA and, like high-titer RF, are linked to erosive RA. Citrullinated antigens expressed in the inflamed joint include fibrinogen, vimentin, α -enolase, and collagen.
- Autoantibodies to carbamylated antigens containing the unusual amino acid homocitrulline may have similar specificity and prognostic value as ACPAs.
- Among other autoantigens, the heterogeneous nuclear ribonucleoprotein-A2 (RA33) may be of pathogenetic relevance because it is also a target of autoreactive T cells.
- Autoantibodies may contribute to the pathophysiology of RA by inducing, maintaining, or modulating the disease process. However, for none of the known autoantibodies has a direct pathogenic role been clearly verified, and the primary (disease-inducing) autoimmune targets remain to be identified.

INTRODUCTION

The presence of autoantibodies and autoreactive T cells in blood and joint fluid is a characteristic feature of rheumatoid arthritis (RA) that distinguishes this disease from other inflammatory or degenerative joint disorders such as psoriatic arthritis, reactive arthritis, or osteoarthritis. As in other systemic autoimmune diseases, most autoantibodies in patients with RA are directed to antigens that are widely expressed throughout the body, but joint-specific structures are not among the primary targets. The hallmark autoantibody of RA, rheumatoid factor (RF), is directed against immunoglobulin G (IgG), and the most specific autoantibodies—anti-citrullinated protein/peptide antibodies (ACPAs)—are directed to citrullinated epitopes contained in proteins such as fibrinogen, vimentin, or α -enolase. Other antigens described as targets of autoimmune responses in RA include carbamylated proteins containing the unusual amino acid homocitrulline, nuclear proteins, heat shock proteins, enzymes, or cartilage components such as collagen type II (CII) (Table 91.1). Although most antibodies appear to be of limited usefulness for diagnostic purposes, they may nevertheless contribute to the pathologic processes characteristic of RA, such as chronic synovitis and erosion of cartilage and bone, by immune complex formation with subsequent induction of proinflammatory immune responses. In the following sections the major antibody systems are described and their value as diagnostic tools, as well as their potential role in the pathogenesis of RA, is discussed.

RHEUMATOID FACTORS

RFs are a family of autoantibodies that recognize antigenic determinants on the Fc portion of IgG (Fig. 91.1). This part of the molecule is essential for

complement fixation and interaction with the Fc receptor and thus for the uptake of immune complexes. In contrast to most other autoantibodies, the major RF species is the IgM isotype, whereas IgG-RF and IgA-RF occur less frequently. RF can be measured by various methods, including agglutination techniques such as the classic Waaler-Rose test, turbidimetric techniques such as laser nephelometry, and enzyme-linked immunosorbent assay (ELISA), which allows determination of RF subtypes.

A transient increase in IgM-RF is part of the normal immune response that occurs during infections, and it is triggered by immune complexes containing microbial antigens. Low-titer IgM-RF can be found in 10% to 15% of healthy individuals, whereas chronic persistence of high-affinity IgM-RF at elevated titer, as well as the presence of IgG and IgA subtypes, is a characteristic feature of RA. Interestingly, genes encoding RF from patients with RA are often somatically mutated, whereas RF from healthy individuals is predominantly germline encoded and polyreactive. Somatic mutation of immunoglobulin genes and a class switch from IgM to other subtypes are indicators of a T cell-driven process that, however, is still not understood in full detail.^{1,2}

Role as diagnostic and prognostic markers

IgM-RF can be detected in 60% to 80% of RA patients with established disease, whereas its prevalence in patients with early RA ranges between 50% and 60%.^{3,4} RFs of all subtypes may already be present in the earliest stages of the disease and can precede the onset of RA by several years.^{5,6} IgM-RF is also present in high titer in the majority of patients with primary Sjögren syndrome or mixed cryoglobulinemia and can be found in lower titer in all other rheumatic autoimmune diseases. At the commonly used cutoff value of 15 or 20 IU/mL, IgM-RF shows only moderate specificity for RA, but specificity is considerably increased at higher titer, and RF above 40 or 50 IU/mL (high-titer RF) has been found to be quite specific for RA.⁷ However, high-titer RF is present in only 50% to 60% of RA patients with established disease and is even less frequent in patients with early RA. Importantly, high-titer IgM-RF, as well as IgA-RF, also has considerable prognostic value because it is associated with the severity of RA, such as erosiveness (Fig. 91.2), more rapid disease progression, worse outcome, and extraarticular manifestations.⁸⁻¹⁰ Therefore, IgM-RF is still the most widely used serologic marker of RA and part of the 2010 American College of Rheumatology/European League Against Rheumatism (ACR/EULAR) criteria for the classification of RA.¹¹

Pathogenetic involvement

The physiologic role of RF during a normal immune response is to enhance the avidity and size of immune complexes, thereby improving clearance of the immune complexes. Immune complexes are also present in the joint, and complement fixation by IgG-containing immune complexes is enhanced by IgM-RF binding. This may be particularly important for immune complexes containing antibodies to cartilage antigens and other proteins expressed in the joint, including antigens that are not joint specific, such as stress proteins, citrullinated proteins, or nuclear antigens. Therefore, RFs may contribute to the activity and chronicity of the disease via complement-mediated pathways (Fig. 91.3). Furthermore, RF-bearing B cells may act as antigen-presenting cells and efficiently present (foreign or self) antigens to T cells via uptake of immune complexes. Because RF in serum and especially RF-producing B cells in the synovial tissue of patients with RA presumably exert such functions, they may thereby contribute to the pathophysiology of RA. Finally, the association of high-titer RF with more severe disease, particularly with bone erosion and extraarticular manifestations, may be considered additional, though indirect, evidence of a pathogenic role of RFs.⁷⁻¹⁰

TABLE 91.1

Targets of autoantibodies in rheumatoid arthritis

Antigen	Antibody	Specificity	T cells
Immunoglobulin G	Rheumatoid factors	Moderate to high*	Unknown
Citrullinated proteins	ACPA	High	Yes
Carbamylated proteins	Anti-carP	Unknown	Unknown
HnRNP-A2	Anti-RA33	Moderate	Yes
Collagen II	Anticollagen	Low	Yes
Stress proteins	Anti-BiP, anti-hsp90, anticalnexin, anti-Grp94	Low	Yes
Glucose-6-phosphate isomerase	Anti-GPI	Low	Unknown
High mobility group box 1 protein	Anti-HMGB1	Low	Unknown
Calpastatin	Anticalpastatin	Low to moderate	Unknown
Peptidyl arginine deiminase 4	Anti-PAD4	Moderate to high	Unknown

*Dependent on cutoff value.

Fig. 91.1 Rheumatoid factor epitopes on IgG-Fc. A molecular model of the CH₂ and CH₃ domains of IgG show (in yellow) the antigenic sequence around His 435, which can be seen to protrude from the surface. Binding sites are scattered within the Cg2 and Cg3 regions of IgG-Fc. The presence of His 435 is an essential constituent of the Ga determinant and absent in IgG3. (With permission of Elsevier Science Ltd, reprinted from Peterson C, Malone CC, Williams RC Jr. Rheumatoid factor reactive sites on CH₃ established by overlapping 7-mer peptide epitope analysis. *Mol Immunol* 1995;35:57-75.)

ANTI-CITRULLINATED PROTEIN/PEPTIDE ANTIBODIES

The discovery in 1998 that citrulline is an essential constituent of epitopes recognized by autoantibodies in serum from patients with RA¹² has increased our understanding of the specific immune reactions that are thought to drive RA and has led to development of the most disease-specific diagnostic test for RA.¹³

Citrullination

Citrullination is the posttranslational conversion of peptidylarginine to peptidylcitrulline, a process catalyzed by a family of calcium-dependent peptidylarginine deiminases (PADs)¹⁴ (Fig. 91.4). This type of protein modification has been linked to apoptosis and terminal differentiation of cells, conditions that enables activation of PAD by increasing intracellular calcium levels. Thus, citrullination *per se* is not specific for RA. Increased citrullination has been associated with inflammation in various tissues, including the lungs, the central nervous system (CNS), and skeletal muscles. Citrullination of specific proteins with specific tissue distribution is also part of normal physiology, for example, citrullination of trichohyalin in the hair follicle, myelin basic protein in the CNS, histones in the nucleus, and keratin/filaggrin in the skin.¹⁵

BOX PLOTS SHOWING THE DIFFERENCE IN LARSEN SCORES IN RA PATIENTS WITH HIGH-TITER RF (>50 U/mL) VERSUS PATIENTS WITH LOW-TITER OR NEGATIVE RF

Fig. 91.2 The boxes show median values and 25th/75th percentiles. Baseline values were similar in both groups, but Larsen score progression was significantly higher in patients with high-titer rheumatoid factor (RF), both in the overall rheumatoid arthritis (RA) population ($P < .0001$) and in the subpopulation of anti-citrullinated peptide antibody-negative patients ($P = .0014$, not shown). (Adapted from Nell V, Machold KP, Stamm TA, et al. Autoantibody profiling as early diagnostic and prognostic tool for rheumatoid arthritis. *Ann Rheum Dis* 2005;64:1731-6.)

History of testing for anti-citrullinated peptide antibodies

The antiperinuclear factor described in 1964 and the antikeratin antibodies identified in RA sera a few years later were both found to target citrullinated filaggrin. Based on this finding, the first citrulline-containing peptide ELISA

Fig. 91.3 (a) Rheumatoid factor (RF) may enhance autoimmune reactions by capturing immune complexes (composed of autoantibodies such as anti-citrullinated protein/peptide antibodies [ACPAs] and self antigens) and subsequently present peptides derived from the autoantigen to autoreactive T cells. (b) RF may bind autoantibodies directed to antigens expressed in the joint (e.g., ACPAs recognizing citrullinated antigens such as fibrinogen, vimentin, or α -enolase) and activate complement, further enhancing the inflammatory process. MHC, major histocompatibility complex; TcR, T-cell receptor.

Fig. 91.4 Enzymatic conversion of arginyl to citrullyl is a posttranslational modification that changes the charge and biochemical properties of proteins. Citrullination is predominantly observed in proteins of the cytoskeleton such as cytokeratin, vimentin, or filaggrin and seems to represent a general regulatory mechanism that particularly occurs during apoptosis. PAD, peptidylarginine deiminase.

Fig. 91.5 Detection of deiminated (i.e., citrullinated) proteins in rheumatoid arthritis synovial tissue as demonstrated by immunoperoxidase staining with an antibody to modified citrulline. (a and b) In positive synovial membranes, the cytoplasm of numerous macrophage-like or fibroblast-like mononuclear cells, located in the lining or in the deep synovium, is intensely stained. (c) In addition, staining of interstitial amorphous deposits located in the vicinity or close periphery of labeled mononuclear cells is observed in the deep synovium. (d) For comparison, a section of human skin is shown in which the entire cornified layer of the epidermis (containing deiminated filaggrin) is stained. Scale bars, 50 μ m. (With permission of the American Association of Immunologists from Masson Bessiere C, Sebbag M, Durieux JJ, et al. In the rheumatoid pannus, anti-filaggrin autoantibodies are produced by local plasma cells and constitute a higher proportion of IgG than in synovial fluid and serum. *Clin Exp Immunol* 2000;119:544-52.)

was developed; it used linear citrullinated filaggrin peptides as antigen. By adopting a cyclic structure of the peptides, the sensitivity of the assay was increased, and the first-generation cyclic citrullinated peptide (CCP) ELISA was developed. The most frequently used ACPA test today is the second-generation CCP assay (CCP2), which is based on synthetic peptides that were identified after screening large peptide libraries.¹³

Citrullinated candidate autoantigens

With high sensitivity (approximately 60% to 70%) and high specificity (approximately 95%),^{3,4,13} the CCP2 assay is now considered a “gold standard” diagnostic test for RA. However, the artificial peptides in CCP2 do not correspond to any human protein sequence but rather mimic *in vivo*-generated citrullinated epitopes. Hence, research has been focused on the identification and characterization of physiologic ACPA targets, with citrullinated epitopes on fibrin(ogen),¹⁶ vimentin,¹⁷ CII,¹⁸ and α -enolase¹⁹ being the best described candidates today.

Extracellular fibrin deposits, including citrullinated forms of fibrin(ogen), are common features of rheumatic joints (Fig. 91.5), and immunodominant B-cell epitopes on the citrullinated α and β chains of fibrin(ogen) have been identified. Another citrullinated antigen of interest is the intermediate filament protein vimentin, first described as the Sa antigen. Vimentin, ubiquitously expressed as a cytoskeletal protein, exists in various citrullinated and mutated isoforms in inflamed joints.²⁰ Based on this observation, the anti-modified citrullinated vimentin (MCV) ELISA was developed. Several studies have now concluded that the MCV and CCP2 tests perform comparatively well in terms of sensitivity and specificity for RA.²¹ As the major component of articular cartilage and the most widely used antigen in experimental models of arthritis, CII represents another attractive candidate autoantigen in RA. Antibodies to the C1 epitope on citrullinated CII have been described in RA, and citrullinated CII peptides have been identified in synovial fluid from patients with RA. Citrullinated α -enolase, with its immunodominant B-cell epitope citrullinated α -enolase peptide-1 (CEP-1), is another well-characterized target of the ACPA response. As a glycolytic

enzyme and a plasminogen receptor on the cell surface, α -enolase is ubiquitously expressed and upregulated in response to proinflammatory stimuli.¹⁵

The frequency of ACPAs reactive with single peptides derived from citrullinated proteins is in most patient cohorts lower (typically around 40%) than the frequency of anti-CCP or anti-MCV antibodies (typically around 60% to 70%). However, the number of RA patients positive for any of these ACPA fine specificities is rather similar to the number of patients positive for CCP (or MCV).²²

Role as diagnostic and prognostic markers

ACPs are generally present early in the disease course and can even be detected years before joint symptoms develop.^{3,6} Although the prevalence of ACPAs in early RA is lower than in established disease, the significance of ACPAs in predicting progression from undifferentiated arthritis—or even arthralgia—to chronic RA has been demonstrated in several studies. These observations, together with high disease specificity (>95%), make ACPAs important serologic markers for early diagnosis and, accordingly, may identify a window of opportunity for early intervention.^{13,23} Even though ACPA-positive and ACPA-negative patients may have similar clinical symptoms at baseline, these two RA subsets demonstrate marked differences in disease course. Radiographic progression (Fig. 91.6), as well as extraarticular manifestations such as ischemic heart disease and lung pathology, is more common in ACPA-positive patients.²⁴ Importantly, the association of ACPA particularly with radiographic progression is not linked to the presence of RF, and therefore both antibodies are independent predictors of erosive disease (Fig. 91.7). The importance of ACPAs as diagnostic and prognostic markers has recently been acknowledged by the EULAR and ACR. In 2010, ACPAs (along with RF) were included in the new classification criteria for RA.¹¹

BOX PLOTS SHOWING THE DIFFERENCE IN LARSEN SCORES BETWEEN ACPA POSITIVE AND ACPA NEGATIVE RA PATIENTS (AS DETERMINED BY THE ANTI-CCP ELISA) WITH LOW-TITER (<50 U/mL) OR NEGATIVE RF

Fig. 91.6 The boxes show median values and 25th/75th percentiles. Baseline values were similar in both groups, but Larsen score progression was significantly higher in ACPA-positive patients ($p = .038$). ACPA, anti-citrullinated peptide antibody; CCP, cyclic citrullinated peptide; ELISA, enzyme-linked immunosorbent assay; RF, rheumatoid factor.

Role in disease etiology and pathogenesis

ACPs may antedate the symptoms and diagnosis of RA,^{5,6} with epitope spreading and increasing antibody titers as clinical onset approaches.²⁵ Hence, the development of ACPA-positive RA seems to progress through two phases: autoimmunity to citrullinated epitopes—in the absence of clinical symptoms—develops in the first phase, and autoimmune disease—characterized by clinical synovitis/arthritis—develops in the second phase (Fig. 91.8). The molecular pathways behind these events are not fully understood, but epidemiologic studies have identified genetic and environmental factors that may contribute.

HLA-DRB1 shared-epitope (SE) alleles constitute risk factors for the development of ACPAs rather than RA *per se*.^{26,27} and more recent data indicate that HLA-DRB1 SE alleles predispose to the development of certain ACPA fine specificities (i.e., anti-CEP-1 and anti-citrullinated vimentin antibodies), but not others (i.e., mainly anti-citrullinated fibrinogen antibodies), thus suggesting that the production of different ACPAs may be governed by partly different mechanisms.^{22,28,29} In view of the role of major histocompatibility complex (MHC) class II molecules in presenting antigens to T cells, it has been hypothesized that HLA-DRB1 SE preferentially presents citrullinated peptides to pathogenic T cells. Some evidence for this hypothesis comes from experimental studies. In DR4-IE transgenic mice, conversion of arginine to citrulline in a vimentin peptide was shown to increase MHC affinity and thereby enhance specific T-cell activation,³⁰ and T cells specific for a citrullinated vimentin peptide, but not the arginine-containing equivalent, were identified in human blood with the use of HLA-DR*0401 tetramers.³¹

Cigarette smoking has also been associated with ACPA-positive RA. The risk conferred by smoking is dependent on HLA-DRB1 SE alleles, and a gene-environment interaction has been demonstrated.²⁶ Increased expression of PAD enzymes and citrullination has been described in the lungs of smokers, thus suggesting exposure of autoantigens to the immune system in an inflammatory milieu, which may initiate loss of tolerance in genetically predisposed individuals (i.e., HLA-DRB1 SE positive) (Fig. 91.9). Increased immunogenicity by citrullination has been demonstrated in experimental animal models and may result from the formation of novel or altered self-epitopes.³²

The mechanisms responsible for the progression from autoimmunity to autoimmune disease are poorly understood, and whether ACPAs are involved is not known. However, circumstantial evidence points to a pathogenic role for ACPAs in RA, including the high predictive value and the association

THE PROBABILITY OF RADIOGRAPHIC PROGRESSION

Fig. 91.7 Change in van der Heijde–modified Sharp score of the hands and feet greater than 10 U/10 yr according to different combinations of the independent predictors IgM–rheumatoid factor (IgM-RF), anti-citrullinated peptide antibody (ACPA), and erythrocyte sedimentation rate (ESR) from a logistic regression model. (From Syversen SW, Gaarder PI, Goll GL, et al. High anti-cyclic citrullinated peptide levels and an algorithm of four variables predict radiographic progression in patients with rheumatoid arthritis: results from a 10-year longitudinal study. *Ann Rheum Dis* 2008;67:212-7.)

DEVELOPMENT OF AUTOIMMUNITY AND DISEASE IN RA PATIENTS

Fig. 91.8 Genetic and environmental risk factors, such as HLA-DRB1 shared epitope and smoking, drive the development of autoimmunity characterized by autoantibodies (anti-citrullinated peptide antibodies [ACPAs], rheumatoid factor [RF], etc.). Later, symptoms of arthritis develop, including arthralgia, and eventually rheumatoid arthritis (RA) is diagnosed. (Courtesy Rikard Holmdahl.)

ETIOLOGIC HYPOTHESIS FOR THE DEVELOPMENT OF ACPAs AND RA

Fig. 91.9 Smoking induces inflammation in the lungs, with increased cell death and activation of peptidylarginine deiminase (PAD) enzymes subsequently leading to increased protein citrullination. In genetically predisposed individuals (i.e., HLA-DRB1 shared epitope positive), loss of tolerance to citrullinated antigens results in the production of anti-cyclic citrullinated protein/peptide antibodies (ACPAs), which later interact with citrullinated proteins present in the joint and thereby cause chronic joint inflammation. RA, rheumatoid arthritis.

with disease severity, as well as the enrichment of ACPAs in joints as compared with the circulation,³³ along with treatment data from studies using rituximab, which depletes CD20-positive B cells and reduces levels of ACPA in responders; conversely, relapse is associated with the return of ACPA-producing B cells.³⁴ Furthermore, in mouse models of arthritis, transfer of a monoclonal anti-citrullinated fibrinogen antibody could enhance disease development, whereas immunization with citrullinated CII increased the incidence and accelerated the onset of collagen-induced arthritis; both

POSTTRANSLATIONAL MODIFICATIONS OF ARGININE AND LYSINE

Fig. 91.10 (a) Citrullination (deimination) is an enzymatic reaction catalyzed by peptidylarginine deiminases in which the NH group of arginine is cleaved. (b) Homocitrullination (carbamylation) occurs via the nonenzymatic addition of a CONH₂ group to lysine. Carbamylation requires cyanate, which can be derived from urea or endogenously generated from thiocyanate via a myeloperoxidase (MPO)-catalyzed biochemical reaction.

citrullinated fibrinogen and α -enolase were shown to induce arthritis in DR4-IE transgenic mice, although it should be noted that this arthritis was mild and nonerosive.¹⁵

It has been hypothesized that ACPAs mediate pathology via the formation of immune complexes and engagement of Fc receptors, with the subsequent production of proinflammatory mediators. In support of this hypothesis, ACPA-mediated immune complexes were shown to induce the secretion of tumor necrosis factor (TNF) in human macrophages via the Fc γ IIa receptor (Fc γ RIIa) and Toll-like receptor 4, and activation of complement by ACPAs has been demonstrated.³⁵⁻³⁷

ANTIBODIES TO CARBAMYLATED (HOMOCITRULLINATED) ANTIGENS

A posttranslational modification very similar to citrullination is carbamylation, or the conversion of lysine to homocitrulline in a nonenzymatic reaction with cyanate, which is in equilibrium with urea in the body (Fig. 91.10). Under physiologic conditions the concentration of urea is too low for extensive carbamylation. Increased levels of cyanate occur with renal insufficiency or during inflammation when the enzyme myeloperoxidase, which catalyzes oxidation from thiocyanate to cyanate, is released from neutrophil granulocytes. Interestingly, plasma thiocyanate levels are also elevated in smokers.³⁸

Carbamylation changes the charge of proteins and, like citrullination, can impede biologic function. Carbamylation has also been shown to enhance the immunogenicity of proteins and increase reactivity to citrullinated peptides.³⁹ Because homocitrullinated proteins have been detected in the joints of patients with RA, carbamylation could have a role in the pathogenesis of RA.

IgG antibodies against carbamylated proteins (anti-CarP) are present in 45% of RA sera and IgA antibodies in 43%. Importantly, anti-carP antibodies do not cross-react with ACPA, and IgG anti-carP antibodies are present in 16% of ACPA-negative patients and, similar to ACPA, seem to be associated with a more destructive disease course.⁴⁰ Anti-carP autoantibodies are therefore an interesting new family of potential marker antibodies in RA, although their specificity for RA is not yet clear and it is presently not known which carbamylated proteins are recognized by anti-carP antibodies *in vivo*. Because the carbamylation reaction is almost irreversible, proteins tend to accumulate homocitrulline residues over time. Stable extracellular matrix proteins

in the joint, such as collagens or fibrinogen, are therefore attractive candidates for carbamylated autoantigens.

ANTIBODIES TO THE HETEROGENEOUS NUCLEAR RIBONUCLEOPROTEIN A2

The heterogeneous nuclear ribonucleoprotein A2 (hnRNP-A2) is a 36-kDa RNA- and DNA-binding protein that exerts multiple functions, including processing, transport, and translation of mRNA. Anti-hnRNP-A2 autoantibodies, which were initially termed anti-RA33, occur in 20% to 30% of RA patients and with comparable frequency also in patients with systemic lupus erythematosus (SLE) or mixed connective tissue disease (MCTD).⁴¹ However, epitope recognition was found to differ in patients with RA, MCTD, and SLE. Because anti-RA33 antibodies are rare in other arthritides such as osteoarthritis, reactive arthritis, ankylosing spondylitis, or psoriatic arthritis, they can be helpful in the differential diagnosis, particularly in patients who are negative for RF or ACPA. Anti-RA33 antibodies have a specificity of approximately 90% for RA, which is lower than the specificity of ACPA or high-titer IgM-RF. Similar to RF and ACPA, anti-RA33 antibodies may already be present in the earliest stages of the disease.⁷ Importantly, they do not correlate with IgM-RF or ACPA and are not associated with radiographic progression but rather seem to predict a more favorable outcome.⁷ Autoimmunity to hnRNP-A2 may be involved in the pathogenesis of RA because pronounced T-cell reactivity has been observed in patients with RA⁴² and the antigen was found to be highly expressed in lymphatic organs and in inflamed synovial tissue. Synovial tissue overexpression and B- and T-cell reactivity to hnRNP-A2 can also be found in animal models of arthritis, namely, in TNF- α transgenic mice and in rats with pristane-induced arthritis.⁴³ In TNF- α transgenic mice, immunization with a peptide corresponding to a major B-cell epitope enhanced the arthritis significantly. Interestingly, in pristane-induced arthritis the autoantigenic (and potentially pathogenic) properties of hnRNP-A2 appear to be dependent on the nucleic acids associated with the protein.⁴⁴

ANTICOLLAGEN ANTIBODIES

Among the 14 different collagens, CII is the major collagen species in the joint and also the major collagen antigen. Anti-CII antibodies are found in many pathologic conditions and are therefore not specific for RA. Titers may be particularly high in early disease and decline as the disease progresses.⁴⁵ However, the prevalence of anti-CII antibodies is not higher in patients with early synovitis in whom RA develops than in those with other early synovitis.⁴⁶ Autoantibodies to collagen and other cartilage components may be contained within the cartilage and contribute to the local macrophage activation and inflammation in RA.

OTHER ANTIBODIES

Other antibodies reported to occur in patients with RA may be directed to quite diverse antigens, including nuclear proteins such as high mobility group box 1 protein (HMGB1), heat shock proteins, enzymes, and enzyme inhibitors (see Table 91.1). In general, these antibodies show low specificity for RA and are therefore of little if any usefulness for diagnostic purposes. An interesting exception is antibodies to PAD4, an enzyme involved in the citrullination of synovial proteins, and these antibodies appear to be rather specific for RA.⁴⁷ Because they are detected mainly in ACPA-positive patients, their diagnostic value is presumably limited. However, the antibodies might inhibit the enzymatic activity of PAD4.⁴⁸

THE IMPACT OF IMMUNOGLOBULIN G GLYCOSYLATION ON ARTHRITIS

IgG possesses a single N-linked glycan at the position asparagine 297 in the CH₂ domain of the two heavy chains (Fig. 91.11a). This glycan consists of a core polysaccharide of N-acetylglucosamine and mannose that can be further modified by the addition of terminal galactosidase or sialic acid (N-acetylneuraminic acid) or the addition of branching fucose (see Fig. 91.11b). More than 30 distinct forms of IgG glycosylation are currently known in humans.⁴⁹ Complete removal of the sugars by exchange of the asparagine through alanine or by treatment with peptide-N-glycosidase F has been shown to dramatically reduce the affinity to Fc γ Rs and the proinflammatory activity of IgG. In RA, three galactosylation subfamilies of IgG

have been classically distinguished: IgG-G0 completely lacks galactose, and IgG-G1 and IgG-G2 carry galactose on one or both arms of the biantennary glycan, respectively. Interestingly, agalactosylated IgGs (IgG-G0) are enriched in patients with RA and other autoimmune diseases.⁴⁹ Higher levels of IgG-G0 appear before onset of the disease and correlate with disease parameters in RA. Interestingly, agalactosylation occurs predominantly in females, and reduction of agalactosylated IgG correlates with remission during pregnancy in humans and mice.^{50,51} Importantly, reduced galactosylation appears to be more frequent in the ACPA fraction of total IgG.^{51,52} A skewed IgG glycosylation profile is also apparent in animal models of arthritis, and agalactosylated IgG can induce disease in an arthritis serum transfer model.⁵³

In contrast to the sugar moiety as a whole, the terminal sialic acid appears to confer antiinflammatory activity. In the healthy state most IgG is fully sialylated, but sialylation is reduced on antigen-specific IgG during the course of an immune response. Sialylated IgG has 5 to 10 times reduced binding affinity to Fc γ Rs. The pathogenicity of IgG-G0 residues is therefore thought to rather be caused by the lack of galactose-bound sialic acid than by galactose itself.⁵⁴ Terminal sialic acid is apparently recognized by the receptor DC-SIGN on macrophages or dendritic cells and induces secretion of the type 2 helper T-cell cytokines that increase expression of the inhibitory Fc γ RIIB.⁵⁵ Desialylation could therefore contribute to disease by enhancing proinflammatory activity.

Apart from galactose and sialic acid, fucose seems to influence IgG function. IgG without fucose has strongly increased affinity for activating Fc γ Rs and therefore higher proinflammatory activity.⁵⁶ Treatment of IgG with EndoS, an endoglycosylase purified from *Streptococcus pyogenes* that removes most of the aspartate 297-linked glycan on IgG but keeps one N-acetylglucosamine with its branching fucose residue intact (see Fig. 91.11b), has been shown to inhibit disease transfer in antibody-dependent mouse models of arthritis.^{57,58} Importantly, IgG2a, the IgG subclass mainly responsible for combating bacterial and viral infections, retains its affinity to Fc γ Rs after treatment with EndoS.⁵⁸ EndoS might therefore be considered an interesting therapeutic tool for the treatment of autoimmune diseases because the risk for opportunistic infections would be relatively low.

Glycosylation of IgG is particularly important for treatment with intravenous immune globulin (IVIG), which has been used as therapy for a growing number of autoimmune diseases in the last years and decades, RA among them as well. A potential mechanism of IVIG is reestablishment of sialin-rich IgG, which is reduced in patients with autoimmune diseases.^{54,57}

AUTOANTIBODIES AND DISEASE PATHOGENESIS

Although autoantibodies are commonly present in the sera and synovial fluid of most patients with RA, their pathogenic role has not been fully elucidated. Among the various autoantibodies described, only ACPAs (and possibly also anti-carP) appear to be truly specific for RA. It is currently unknown which citrullinated antigens initiate the ACPA response, but it is presumably not fibrin(ogen) because fibrin deposition and citrullination occur after the onset of joint inflammation and therefore are a consequence rather than the cause of arthritis. Thus, autoimmunity to citrullinated epitopes might be induced by ubiquitously expressed antigens such as vimentin or α -enolase. Once set in motion, this autoimmune response seems to inevitably lead to the development of RA because ACPAs are only rarely observed in healthy subjects or patients with other rheumatic diseases. The strong association of ACPA with certain HLA-DR alleles and with smoking provides a compelling link between genes, the environment, and disease. Remarkably, upregulation of PAD2 and the presence of citrullinated proteins have been demonstrated in the lungs of cigarette smokers and might represent the first event in the pathogenic chain of RA. Binding of ACPAs to their targets in synovial tissue probably has proinflammatory effects that lead to B- and T-cell stimulation and induce extravasation of fibrinogen, fibrin formation, and further deimination. This is most likely a self-maintaining process that is at least partly responsible for the chronicity of the disease (Fig. 91.12). The observation that citrullinated forms of collagen may be present in the synovial fluid of patients with RA suggests that collagen may become a target of ACPAs as well, which may take place later in the course of the disease. Immune complexes consisting of ACPAs and citrullinated antigens may represent the main target for RF, which would explain the close association of these two antibodies.

The lack of disease specificity of autoantibodies other than ACPAs does not necessarily exclude a pathogenic role for them, and also in other systemic autoimmune diseases only few antibodies are truly disease specific.

Fig. 91.11 (a) N-linked glycosylation occurs at asparagine 297 in both of the CH₂ domains of the heavy chains of the IgG molecule. (b) The sugar moiety of the IgG-Fc fragment. Shown are all sugar residues that might be present in the different IgG glycoforms found in serum. The core sugar contains four *N*-acetylglucosamine (NAG) and three mannose (man) residues. Terminal galactose (gal) and sialic acid (sa) or branching fucose (Fuc) or an additional NAG can be present. The cleavage sites of PNGase, EndoS, galactosidase, and neuraminidase are also indicated. Depending on the presence or absence of terminal gal and sa residues, IgG-G1/2 and IgG-G0 isoforms can be distinguished.

Fig. 91.12 In rheumatoid synovial tissue, fibrin is deiminated by the peptidylarginine deiminase (PAD) isoforms PAD2 and PAD4, which are abundantly expressed by synovial monocytes/macrophages and granulocytes, and it becomes the target of the disease-specific antibodies (AhFibA) locally produced by synovial plasma cells (Pc). This leads to antigen/antibody complexes, which via activation of effector mechanisms probably involving complement or Fc receptors (or both), have proinflammatory effects. In turn, these effects lead to plasma extravasation and fibrinogen polymerization and therefore provoke the formation of new fibrin deposits in the tissue, which become the substrate of one or several locally expressed PADs. This closes a vicious circle that could account for the self-maintenance of rheumatoid inflammation. In the synovial tissue of patients without rheumatoid arthritis (RA), even if deiminated fibrin is present, the absence of AhFibA prevents the establishment of this self-maintenance loop. Fg, fibrinogen.

For example, antiphospholipid antibodies are among the pathogenic key players of antiphospholipid syndrome but are also frequently found in patients with SLE. Therefore, antigens such as hnRNP-A2, collagen, or heat shock proteins may also contribute to the disease process by virtue of immune complex formation similar to ACPA.

Taking all these observations into consideration, a general model for the initiation of arthritogenic autoimmune responses is suggested in which an environmental trigger (e.g., a toxic substance or an infectious agent) induces

alterations in tissues (e.g., the lung or lymphoid organs) that lead to extensive modification (e.g., deimination, carbamylation, or phosphorylation) and degradation of proteins and inappropriate release of intracellular material because of apoptosis or necrosis. Uptake of apoptotic or necrotic material by dendritic cells will lead—in those with a susceptible genetic background—to activation of pathogenic T cells and autoantibody production, thereby setting in motion a chain of events that will eventually result in overt disease and irreversible joint damage.

Cellular immunity in rheumatoid arthritis

■ J.S. HILL GASTON

- Susceptibility to autoantibody-positive arthritis correlates with particular major histocompatibility complex antigens that control T-cell recognition of antigens, including autoantigens.
- Cells of the immune system (B and T lymphocytes, dendritic cells, macrophages) are prominent in rheumatoid synovial membrane.
- Therapies directed against the cellular immune response system alleviate symptoms and prevent disease progression in animal models of arthritis and human rheumatoid arthritis.

INTRODUCTION

The immune functions critical to the pathogenesis of rheumatoid arthritis (RA) continue to be debated. What are the roles of innate versus acquired immune responses? Which is dominant? Does RA require an antigen-specific immune response? If so, what antigens are involved? Are they exogenous (e.g., from pathogens) or autoantigens? Alternatively, does RA result from activation of the immune system by stimuli unrelated to the joint and is inflammation maintained by nonspecific mechanisms that can produce proinflammatory cytokines, such as the antigen-independent interactions between activated T cells and synoviocytes? Given that immune responses to foreign antigens or autoantigens do not usually give rise to chronic unresolved inflammation, is the defect in RA a failure to regulate immune responses that would normally be manageable? Such failures could reflect imbalances in cytokines or lack of an adequate response by regulatory T or B cells.

These questions will be considered in this chapter. Animal models of RA will be used to illustrate the processes that can give rise to joint inflammation and destruction. Note, however, that “rodents don’t get RA”; that is, observations in animal models need validation in human disease.

POSSIBLE ANTIGENIC TARGETS OF THE IMMUNE RESPONSE IN RHEUMATOID ARTHRITIS

Much evidence suggests that a T cell–mediated immune response is critical to the pathogenesis of RA, but the antigen or antigens to which this response is generated remain unclear. Candidates include autoantigens, whether specific to the joint or more widely distributed, and foreign, pathogen-derived antigens (Box 92.1).

Autoantigens

RA has no “obvious” precipitant, such as a preceding specific infection. This, together with rheumatoid factors, the first autoantibody to be described, led to the assumption that the disease is autoimmune even though RA lacks tissue-specific autoimmune responses of the kind seen with diabetes and autoimmune thyroid disease. Rheumatoid factors, or antibodies to the Fc domains of IgG, cannot readily be linked to synovitis or cartilage destruction and commonly occur in chronic infections (e.g., endocarditis) without causing arthritis. Likewise, anti–citrullinated protein antibodies (ACPAs), which target posttranslationally modified (citrullinated) proteins, lack tissue specificity because such proteins are found at many sites outside joints. ACPAs are now generally measured with the use of artificial citrullinated cyclic peptides.

It is now very clear that “autoantibody-positive” RA is a different disease from “seronegative” RA. The latter lacks association with the HLA-DR shared epitope, nor is smoking implicated in the disease.¹ Therefore, when considering the pathogenesis of RA, careful distinction between findings in seropositive and seronegative disease should be made.

Joint components

Type II collagen

Arthritis is readily induced in rodents and primates by immunization with heterologous or homologous native type II collagen; such arthritis requires both collagen-specific B and T cells. Susceptibility depends on major histocompatibility complex (MHC) antigens, and the disease can be modulated by depleting specific T cells or inducing tolerance via the oral administration of type II collagen. Despite the attractiveness of the model, the importance of immune responses to type II collagen in RA remains unclear. Collagen-specific T and B cells can be isolated from some RA patients, especially if responses to glycosylated or other posttranslationally modified forms of type II collagen are examined.² Such cells may be more prevalent in synovial tissue but are not invariable, and attempts to induce oral tolerance to type II collagen did not produce consistent effects on RA activity. They might even arise secondary to joint destruction and exposure of otherwise cryptic epitopes in type II collagen to the immune system. Together, these findings do not strongly support type II collagen as the target autoantigen in RA. However, type II collagen can also be posttranslationally modified by citrullination; antibodies to citrullinated type II collagen are more frequent than those to unmodified collagen and highly correlated with ACPA titers,³ whereas citrullinated type II collagen induces more severe arthritis in rats than the native protein does. Thus, citrullinated type II collagen may be a true “target antigen” in RA.

Proteoglycans and chondrocyte proteins

Erosive arthritis, as well as spondylitis, develops in mice immunized with the human cartilage proteoglycan aggrecan, which suggests that this is a model of spondyloarthritis rather than RA. Other cartilage proteoglycan molecules, such as biglycan and decorin, could be targets in RA, and antibodies to a citrullinated biglycan peptide have been seen in patients in whom RA later developed. Human cartilage glycoprotein 39 (HCgp39) also induces arthritis in mice, and certain HCgp39-derived peptides bind strongly to the RA-associated HLA allele DRB1*0401. These peptides are recognized by T cells from some RA patients, but synovial HCgp39-specific T cells could not be identified in most DR4+ RA patients when using tetramers of HCgp39-derived peptide bound to DRB1*0401.⁴ Thus, the status of HCgp39 as a target antigen is unclear.

Proteins not restricted to the joint

If joint-specific constituents are not readily implicated as autoantigens in RA, more widely distributed antigens deserve consideration.

Glucose-6-phosphate isomerase

In the K/BxN mouse, arthritis occurs because of autoimmunity to a ubiquitous cellular antigen, glucose-6-phosphate isomerase (G6PI) (Box 92.2).⁵ This arthritis involves G6PI-specific T and B cells; even though disease can be transferred passively with antibody, it is transient when compared with what develops in the K/BxN mouse, which has autoreactive T cells. The pathogenic T cells are type 17 helper T (Th17) cells whose development requires certain gut bacteria.⁶ Even though G6PI is ubiquitous and not overexpressed in the joint, inflammation occurs mainly in the joint (and also the salivary glands). The autoreactive T cell drives the production of G6PI-specific autoantibodies, which can form immune complexes and activate synoviocytes and mast cells in a complement-dependent fashion.

BOX 92.2 SEQUENCE OF EVENTS IN THE DEVELOPMENT OF A MODEL OF EXPERIMENTAL ARTHRITIS CAUSED BY AUTOIMMUNE RECOGNITION OF A NORMAL CELLULAR ENZYME

1. A mouse T-cell receptor (termed KRN) was characterized that recognizes an experimental antigen (bovine ribonuclease) presented by the class II MHC antigen I-A^k.
2. I-A^k mice transgenic for the KRN T-cell receptor were produced (i.e., all their T cells express the same receptor); the mice were completely healthy.
3. In KRN T-cell receptor transgenic mice expressing a different class II MHC antigen (I-A^{B7}), an aggressive rheumatoid arthritis–like inflammatory arthritis developed (the “K/BxN” mouse).
4. Arthritis was produced because the KRN T-cell receptor can recognize a peptide from an autoantigen presented by I-A^{B7}—that is, “accidental” cross-reactivity of the T-cell receptor.
5. The autoantigen was identified as a ubiquitous cellular enzyme: G6PI.
6. Both antibody and T-cell responses to the autoantigen are required to produce arthritis (no disease occurs in B cell–deficient mice), and disease can be transferred with T cells or serum.
7. The arthritogenic T cells specific for G6PI make interleukin-17 and require gut flora to develop.

G6PI, glucose-6-phosphate isomerase; MHC, major histocompatibility complex.

Because the G6PI autoantibodies are clearly arthritogenic, the model suggests that RA need not require autoimmunity to a joint-specific antigen.

Citrullinated proteins

ACPAs are now recognized as a highly specific feature of RA. Citrullination is a posttranslational modification of a protein (deimination of arginine carried out by peptidylarginine deiminases [PADs]); such modifications are increasingly being recognized as targets of autoimmunity.⁷ Although most ACPA-positive patients are also rheumatoid factor positive, ACPAs have higher specificity for RA. Like rheumatoid factors, they can appear years before RA develops and are associated with erosive disease. ACPAs were first recognized as autoantibodies to keratin (which has many citrullines residues), but the relevant target of ACPAs in RA is still being debated. As noted earlier, immune responses to citrullinated type II collagen and biglycan are described, but responses to other citrullinated proteins unrelated to joints have also been examined, including vimentin, fibrinogen, aggrecan, heat shock proteins (hsps), and α -enolase.⁸ For α -enolase the immunodominant citrullinated peptide recognized is conserved in α -enolase from the bacterium *Porphyromonas gingivalis*, an etiologic agent of periodontitis, which is a condition common in patients with RA. Intriguingly, this bacterium uniquely possesses its own deiminase (i.e., a bacterial PAD). Enolases are common targets of the immune response to bacteria.

Because ACPAs are of high affinity and class switched, involvement of T cells in their generation can be assumed. T cells can recognize citrullinated peptides,⁹ although responses in RA patients were relatively weak and the particular antigen recognized varied from patient to patient. A shared epitope–containing HLA-DR allele was shown to bind a citrullinated peptide more strongly than the equivalent peptide containing arginine and to provoke an immune response (Fig. 92.1). If the unmodified peptide fails to bind strongly to the MHC in the thymus, T cells specific for that self-peptide will not be negatively selected and may later be available to recognize the citrullinated peptide that binds the MHC tightly—the citrulline residue confers binding to the MHC but does not need to contribute to what the

Fig. 92.1 A citrullinated self-peptide may bind tightly to class II major histocompatibility complex (MHC) alleles such as HLA-DR4 and can be presented to autoreactive T cells, whereas a weakly binding unmodified peptide would not occupy HLA-DR4 molecules long enough to stimulate autoreactive T cells. Likewise, the autoreactive T cells would not be not deleted centrally and would be released into the periphery if within the thymus only the weakly binding unmodified peptide were available for presentation and the citrullinated peptide were absent. Citrullination requires specific enzymes (peptidylarginine deaminases), which may not be available in the thymus. Ag, antigen.

T-cell receptor (TCR) “sees.” That tolerance can be broken in this way is illustrated by induction of arthritis in HLA-DR4 transgenic mice via citrullinated fibrinogen.¹⁰

Heat shock proteins

Hsps are ubiquitous cellular constituents; immune responses to an hsp (mycobacterial hsp60) were shown to cause adjuvant-induced arthritis in the rat. The amino acid sequences of hsps are highly conserved, so it was initially thought that bacterial hsp-specific T cells would cross-react with human hsp (see “Molecular Mimicry” later). However, more recent evidence suggests that self-hsp-specific T cells often *protect* against induction of arthritis.¹¹ Indeed, CD4+CD25+Foxp3+ regulatory cells may recognize self-hsp when being selected in the thymus.

Unidentified self-antigens

The SKG mouse, which has a mutation in the ZAP-70 signaling molecule downstream of the TCR, is unable to delete autoreactive T cells in the thymus, and therefore autoimmunity develops in this mouse, especially arthritis, with rheumatoid factors and antibodies to type II collagen.¹² The antigens recognized by T cells in this model are not known, but they make interleukin (IL)-17.¹³ Unlike the K/BxN mouse, disease is not transferable by serum; indeed, IL-6–deficient SKG mice have high titers of rheumatoid factor but no arthritis.

Summary

No autoantigen has been proved to be central to the pathogenesis of RA. Indeed, different joint antigens might be involved at various stages, perhaps through “epitope spreading,” in which autoimmune responses to one self-epitope are followed later by responses to separate epitopes in the same autoantigen or to other antigens in the same tissue. Some responses to autoantigens in RA may arise secondary to joint destruction and exposure of normally “hidden” antigens to the immune system (e.g., chondrocyte antigens).

Exogenous antigens

An infective etiology of RA has often been postulated, but no etiologic organism has been convincingly implicated.

Bacteria

Bacteria are attractive sources of putative RA-inducing antigens; mycobacterial and streptococcal antigens induce experimental inflammatory arthritis, as do organisms within the normal gut flora. Because RA does not exhibit the epidemiologic features of an infectious disease, a candidate etiologic agent should be ubiquitous and well tolerated by most of those infected. Disease would then occur only in those with susceptibility genes (e.g., *HLA-DR4*, *PTPN22*, *PADI4*) or additional environmental exposures (or both). Compare peptic ulcer disease and *Helicobacter* infection: even when many people carried *Helicobacter*, ulcer disease occurred mainly in smokers.

Reverse transcriptase polymerase chain reaction (RT-PCR), which amplifies conserved ribosomal RNA from all bacteria, has detected many bacterial rRNA sequences in RA synovium¹⁴ but no unique “RA-associated” organism. Instead, the presence of bacterial rRNA correlated with joint inflammation rather than a specific arthritis, whereas normal synovium was negative. This suggests that inflamed synovium receives bacteria (or bacterial nucleic acids), particularly from gut and skin commensals, that are probably brought to the joint within phagocytes because the inflamed synovium continuously recruits monocytes and dendritic cells. Although the organisms may be briefly viable (bacterial rRNA has a relatively short half-life), they do not replicate, and the joint remains sterile by conventional culture.

Such secondary “colonization” of inflamed synovium by bacteria could contribute to the pathogenesis of RA. Bacterial components are potent activators of the innate immune system and serve as adjuvants that allow adaptive T- and B-cell responses to be made. Such components include lipopolysaccharide, peptidoglycan, and bacterial DNA, all acting via Toll-like receptors (TLRs) to induce monokine secretion and upregulation of co-stimulatory molecules on antigen-presenting cells.¹⁵ Activation of antigen-presenting cells such as dendritic cells by bacterial DNA and other TLR ligands (i.e., an adjuvant function) might allow responses to self-antigens to be generated within the joint. Finally, given the findings regarding recognition of citrullinated α -enolase (see earlier), bacteria with α -enolases containing the same epitope as that found in *P. gingivalis* could contribute to joint inflammation on transport to the joint, particularly if tissue PAD enzymes could convert arginines in the bacterial α -enolase to citrullines.

Even though the possibility of bacteria as direct triggers of RA needs consideration, much attention is currently being paid to the critical role of commensal organisms, especially those of the gut, in shaping the immune system,¹⁶ particularly the generation of IL-17-producing cells.⁶ It remains possible that alterations in gut flora play a part in the pathogenesis of RA in this way, even if these organisms are not themselves recognized as antigens by the immune system.

Viruses

Several viruses cause joint inflammation (e.g., rubella, parvovirus B19, chikungunya); as with bacteria, PCR has been used to detect viruses in RA synovium with generally negative or inconsistent results. Herpesviruses such as Epstein-Barr virus (EBV) cause ubiquitous lifelong infection, thus making EBV an attractive candidate organism for RA. Abnormal immune responses to Epstein-Barr nuclear antigen-1 (EBNA-1) have been noted in RA. This antigen contains glycine-arginine repeats similar to those seen in several citrullinated autoantigens (e.g., keratin, fibrillarin). EBNA-1 can be citrullinated intracellularly and is then recognized by ACPAs from patients with RA.¹⁷ Expansions of EBV-specific T cells, particularly CD8+ T cells, have been identified in RA synovium, but this is not surprising because the joint is enriched with memory T cells, and those recognizing persistent viruses such as EBV and cytomegalovirus dominate the normal CD8+ T-cell repertoire. Thus, a role for EBV in the pathogenesis of RA remains unproven.

Molecular mimicry

Infectious agents have often been postulated to be involved in the pathogenesis of arthritis through “molecular mimicry” (i.e., foreign antigens “mimicking” joint autoantigens because of similarity in their amino acid sequences). In this way, immune responses correctly directed against components of a pathogen could cross-react with self-proteins and lead to autoimmunity. Molecular mimicry can be demonstrated by showing antibodies that bind to short linear peptides derived from a bacterial or viral protein and also to an autoantigen (Fig. 92.2a). Even though mimicry is also possible with regard to shared conformational epitopes (those not

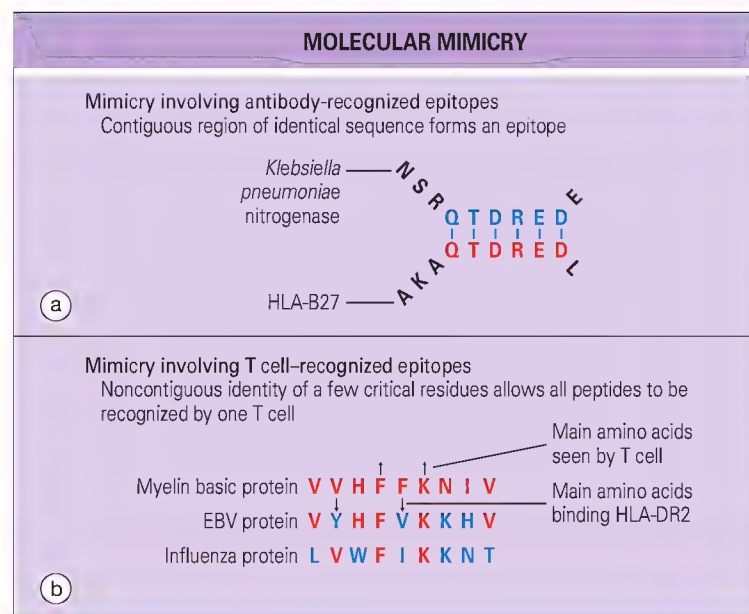

Fig. 92.2 Molecular mimicry of self-peptides by foreign peptides has different requirements for antibodies recognizing linear epitopes and for T-cell recognition. EBV, Epstein-Barr virus.

determined by simple similarity between linear peptides), this is not predictable from sequence data.

However, when molecular mimicry at a T-cell level is considered, the situation is more complex. T cells also recognize short linear peptides bound to the MHC, but only a small number of amino acids within a peptide are actually necessary for T-cell recognition: those that allow binding to the MHC and those that make contact with the TCR (see Fig. 92.2b). This means that two peptides with a very low level of overall sequence identity can both stimulate a given T cell provided that these critical residues are conserved; indeed, each TCR potentially recognizes many different peptides. For binding to the MHC there is a set of preferred amino acids, so the main determinants of specificity are the small number of amino acids that interact with the TCR, and these are not usually contiguous. Thus although searching protein databases for bacterial or viral peptides that share a high degree of sequence identity with a self-protein can reveal epitopes that are candidate mimics as far as antibody recognition of linear epitopes is concerned, for molecular mimicry at the T-cell level it is necessary to identify the critical MHC binding and TCR-interacting residues and then look for peptides that have these features, even if they have little overall sequence identity. In practice, almost all T cell-recognized epitopes in pathogens will have a potential “mimic” within some self-protein; that is, potential molecular mimicry is something with which the immune system deals routinely. In many cases the mimicking self-peptide is never presented to the immune system because antigen processing does not generate the cross-reactive self-peptide. If the self-peptide is generated by processing, both thymic and peripheral tolerance mechanisms will normally ensure that it is not recognized in either the self-protein or the mimicking pathogen. Thus, despite its obvious attraction as an explanation for autoimmunity, the idea of molecular mimicry lacks experimental support.¹⁸

Summary

Several potential mechanisms implicating infectious agents in the etiology of RA have been proposed, but none has been proved. The full implications of the traffic of phagocyte-associated bacteria or bacterial components to the inflamed synovium have yet to be explored, whereas the role of gut flora in shaping the immune system is an area in which knowledge is developing rapidly.

ANTIGEN-INDEPENDENT EFFECTS OF T CELLS IN RHEUMATOID ARTHRITIS

The most abundant cytokines in the joint that correlate with cartilage and joint destruction are the monokines tumor necrosis factor- α (TNF- α) and IL-1. Transgenic overexpression of TNF- α produces synovitis in mice, as does absence of the natural inhibitor of IL-1, IL-1 receptor antagonist. In RA, unlike these experimental transgenic systems, monokine production is

unlikely to be autonomous, at least in early synovitis, and is considered to be under T-cell control. However, T cells drive monokine production by antigen-presenting cells without necessarily recognizing specific antigens. Activated T cells (CD69+HLA-DR+) from synovium (see later) elicit monokine production from monocyte/macrophages and also interact with fibroblast-like synoviocytes to induce the production of metalloproteinases. The mechanisms underlying these effects remain unclear, but they require contact with T-cell membranes, either intact cells, membrane preparations, or microparticles shed by T cells.¹⁹ T cells may acquire this capacity as a result of the cytokine environment within the joint, because *in vitro* treatment with various “cocktails” of cytokines (e.g., IL-2, IL-6, and TNF- α) produces T cells capable of stimulating monokine production by monocytes or synoviocytes.²⁰ Many of these cytokines are present in the RA joint and might therefore contribute to antigen-independent activation of T cells. T cells eluted from RA synovial membrane have properties similar to those activated *in vitro* by cytokines in terms of their ability to induce TNF- α production by monocytes. Interestingly, the signaling pathways induced in monocytes by T cells activated via their TCR or via cytokines differ; nuclear factor κ B (NF- κ B) is critical to the latter, whereas phosphatidylinositol 3'-kinase (PI3-K) is required for the effects of TCR-stimulated T cells. The future introduction of PI3-K inhibitors to RA treatment might shed light on whether cytokine-activated or antigen-activated T cells are important in RA.

PROPERTIES OF SYNOVIAL T CELLS IN RHEUMATOID ARTHRITIS

Leaving to one side what activates T cells in RA (antigen vs. cytokines), clues to the pathogenesis of RA could come from examining different aspects of their phenotype in RA, especially at sites of disease. The features examined include TCR expression, activation and differentiation marker expression, and cytokine production.

T-cell receptor studies in rheumatoid arthritis

The use of TCR genes by peripheral blood or synovial T cells has been studied to determine whether patients with RA possess a disease-specific population of T cells that express identical or related receptors. The TCR is made up of two chains, α and β (or γ and δ), and rearrangement of the TCR genes (V, D, and/or J genes), plus nucleotide insertions or deletions in each case, produces unique α and β chains and hence a unique $\alpha\beta$ or $\gamma\delta$ TCR. Random recruitment of T cells to the joint would produce a population expressing many different TCRs, whereas recruitment of T cells all recognizing a small number of peptide epitopes would result in overrepresentation of identical or related TCRs (i.e., an oligoclonal rather than a polyclonal T-cell population). In experimental autoimmune diseases, autoantigen-specific T cells are often oligoclonal, but no oligoclonal expansions of T cells with the same or related CDR3 sequences has been reported in RA (discounting early studies, which probably detected expansions produced *in vitro*). However, the advent of next-generation sequencing allows a much more thorough examination of this question by sequencing many thousands of TCRs from synovium or blood, thereby producing greater power to detect small expansions of particular or related TCRs. A recent study showed expansions of several clones in synovium, especially in early disease; the same clones were seen in different joints of the same patient.²¹ This suggests that recognition of specific peptides is a feature of at least the early pathogenesis of RA.

Studies of the surface phenotype of lymphocytes in rheumatoid arthritis

The RA joint contains both natural killer (NK) cells and T cells. Synovial NK cells are CD56bright and CD16⁺,²² a subset that secretes cytokines, especially interferon- γ (IFN- γ), rather than mediating cytotoxicity. The role of NK cells in RA has not yet been clarified; effects on monocytes, fibroblasts, and osteoclasts could contribute to the inflammation and joint destruction, whereas IFN- γ production would decrease Th17 cell differentiation and could modulate IL-17-driven inflammation (see later).

Within the T-cell population, memory T cells predominate and are particularly highly differentiated; they have very low levels of expression of CD45RB, similar to those seen *in vitro* after T cells have undergone several rounds of division, and shorter telomeres, also reflecting increased numbers of divisions,²³ possibly exacerbated by a deficiency in telomerase (the enzyme that can maintain telomere length).²⁴ Such “end-stage” cells should undergo apoptosis, but synovial T cells are protected by factors within the synovial environment, including type I interferons and IL-15 produced by

synovial macrophages and fibroblasts.²⁵ CD4+ T cells that have lost expression of CD28 also resist apoptosis, and CD28⁻ cells are enriched in synovium and may be pathogenic because they are autoreactive, produce IFN- γ , and may be cytolytic.²⁶ Memory T cells are recruited to the synovium as a result of expression of adhesion molecules and are retained there through the actions of chemokines. Unusually, memory T cells in synovium continue to express CXCR4, which is normally lost during differentiation, and remain responsive to its ligand CXCL12 (SDF-1) produced by synovial fibroblasts.²⁷ This results in their retention within the tissue, where they may exert the antigen-independent effects noted earlier and induce synoviocytes to produce monokines and matrix metalloproteinases.

Cytokine production in rheumatoid arthritis

Initial studies of the cytokines produced by synovial T cells were surprising, particularly within the prevailing paradigm of the two major T-cell subsets: type 1 helper T (Th1) cells (proinflammatory and producing IFN- γ , lymphotoxin, and IL-2) and Th2 cells (allergy related and producing IL-4, IL-5, IL-10, and IL-13). RA was expected to be driven by Th1 cells, but IFN- γ concentrations in synovial fluid were very low in comparison to IL-1 and TNF- α , and IFN- γ +CD4+ T cells, detected by intracellular staining, were present only in small numbers. Interestingly, a similarly low proportion of IFN- γ -secreting T cells is seen in murine collagen-induced arthritis, a model that is completely T cell dependent. IL-4+ cells were also absent from the synovial T-cell population in established RA, although investigation of very early arthritis has shown that IL-4 and IL-13 (and IL-17) can be present and predict progression to established RA²⁸; these cytokines were not present at later time points. These puzzling observations have been clarified by the discovery of additional T-cell subsets, particularly Th17 cells. IL-17, unlike IFN- γ , is essential for collagen-induced arthritis²⁹; in fact, absence of IFN- γ exacerbates the disease. Th17 cells have also been clearly implicated in the K/BxN⁶ and SKG¹³ murine models of RA.

IL-17 is a particularly attractive candidate as a T cell–dependent arthritogenic cytokine. It shares some properties of IL-1 and TNF- α , including induction of cartilage degradation, and synergizes with these cytokines. It is also relevant to the erosive bone destruction of RA because it induces the expression of receptor activator of NF- κ B ligand (RANKL) by osteoblasts; RANKL is critical for the differentiation of osteoclasts.³⁰ IL-17 levels in joints and the proportion of Th17 cells in joints and peripheral blood are elevated in RA, and trials of IL-17–blocking antibodies have shown efficacy.³¹

If Th17 cells are indeed central to the pathogenesis of RA, factors that influence their generation become important. Initial studies involving mice implicated transforming growth factor- β (TGF- β) and IL-6 in their differentiation, with a role for IL-23 only in survival and expansion. More recent work, again murine, has shown that IL-23 + IL-6 + IL-1 not only allows differentiation of Th17 cells in the absence of TGF- β but also generates a different kind of Th17 cell with more proinflammatory properties than those generated with TGF- β .³² The pathogenicity of the subset has been linked to the production of granulocyte-macrophage colony-stimulating factor (GM-CSF), although these observations were not made in an arthritis model. Nevertheless, the complete resistance to collagen-induced arthritis seen in mice unable to produce IL-23 suggests that the “more proinflammatory” Th17 subset is also needed for arthritis. IL-23 is made by dendritic cells and macrophages in response to TLR agonists, which also stimulate secretion of the Th1-driving (and Th17-inhibiting) cytokine IL-12. Thus, genetic and environmental influences on dendritic cells that alter the proportions of IL-12 and IL-23 produced may in turn affect the pathogenesis of RA.

Even though these lines of evidence emphasize the importance of IL-17–producing cells in arthritis, such cells are not present in large numbers in either blood or synovial fluid—usually a small percentage of the CD4+ T-cell population. This may relate to the relative plasticity of the Th17 subset, with loss of IL-17 production and substitution of secretion of GM-CSF or IFN- γ (or both), a process that may also require IL-23.³³ Such “ex-Th17” cells may contribute significantly to pathogenesis (Fig. 92.3).

REGULATORY T CELLS IN RHEUMATOID ARTHRITIS

Not all T cells within the joint are necessarily pathogenic; regulatory T-cell (Treg) subsets are known to protect against autoimmune disease, so some synovial CD4+ T cells could be beneficial, though obviously inadequate to stop arthritis. Tregs in peripheral blood³⁴ are CD4+CD25hi, express a transcription factor (Foxp3) that is critical to regulatory function, and suppress proliferation and cytokine production in a contact-dependent manner (Table 92.1). Two forms of Foxp3+ Tregs are recognized: those that develop

DIFFERENT EFFECTOR CELLS DIFFERENTIATE FROM NAIVE T CELLS

Fig. 92.3 Under the influence of cytokines, different effector cells differentiate from naive T cells and express transcription factors (not shown) that determine their function—cytokine secretion or inhibition of helper T-cell proliferation and cytokine production in the case of induced regulatory T cells (iTregs). Plasticity and interconversion of T-cell subsets are illustrated; for example, iTregs to Th17 and Th17 to “ex-Th17” with changes in effector function. GM-CSF, granulocyte-macrophage colony-stimulating factor; IFN- γ , interferon- γ ; IL-2, interleukin-2; TGF- β , transforming growth factor- β ; Th1, type 1 helper T cell.

within the thymus (natural Tregs) and those generated in the periphery (induced Tregs), mainly through the actions of TGF- β . Mutations in the *FOXP3* gene cause severe spontaneous inflammatory and autoimmune disease in mice and humans. A relationship between Th17 and Tregs has been suggested because TGF- β can be involved in the generation of both subsets but IL-6 favors Th17 generation over Tregs.³⁵ Thus, an inflammatory environment containing IL-6 would enhance the generation of Th17 cells and increase inflammation while decreasing the generation of Tregs; these mechanisms might account for the efficacy of IL-6 blockade in RA.

Like synovial T cells, Tregs proliferate poorly *in vitro* and commonly produce IL-10, although this is not required for their regulatory function. Distinguishing Tregs in synovial fluid is difficult because activated human T cells (unlike their murine counterparts) express Foxp3. Increased numbers of CD4+CD25+ cells have been reported in synovial fluid, and they express other markers associated with Tregs (CTLA-4 and GITR), although again these markers appear on activated T cells.³⁶ They show regulatory function in *in vitro* assays, but it is unclear whether they are natural or induced Tregs. Other studies have suggested a functional defect in peripheral blood Treg

TABLE 92.1

Properties of human effector and regulatory CD4+ T cells

	Regulatory CD4+ T cells	Effector CD4+ T cells
CD25 expression	Constitutively high level	Only on activation
CTLA-4 expression	High, constitutive	Late, after activation
Responses to mitogens and anti-CD3	Poor	Vigorous
Foxp3 expression	Positive	Negative, except on activation
Typical cytokines	IL-10, TGF- β	IL-2, IFN- γ , IL-4, IL-17
Thymus dependent	Yes	Yes
Specificity	Self-peptides on class II MHC	Non-self-peptides on class II MHC
Affinity for self-antigens	Moderate	Low

IFN- γ , interferon- γ ; IL-10, interleukin-10; MHC, major histocompatibility complex; TGF- β , transforming growth factor- β .

function in RA, which was reversed by treatment with anti-TNF- α (specifically, infliximab). This was due to the appearance of induced Tregs mediating suppression through IL-10 and TGF- β production rather than by the contact-dependent mechanism used by natural Tregs.³⁷ Thus, within the joint, both pathogenic proinflammatory T cells and Treg populations (natural or induced) coexist. Their proportions may vary in different phases of disease and in response to different treatments and thereby influence activity and progression of disease. Measures to manipulate Treg function and hence ameliorate disease are under investigation but carry potential risks in view of the close relationship between Tregs and the Th17 subset. Tregs generated *in vitro* and transferred to decrease inflammation might differentiate into Th17 cells *in vivo* in a proinflammatory cytokine milieu³⁸ and instead exacerbate disease.

CONCLUSION

T cell-mediated immune responses are strongly implicated in the pathogenesis of RA both by the association of disease with HLA-DR and by the presence and properties of T cells in the synovium.

Whether the critical immune response in RA is directed against autoantigens or exogenous antigens is still unclear. Experimental models of arthritis show that immune responses to ubiquitous self-antigens and those expressed preferentially in the joint can both drive arthritis.

Synovial T cells are mainly highly differentiated memory cells and reflect recruitment to the joint and factors in the synovium that inhibit apoptosis. While activated, they make little IL-2 or IFN- γ ; instead, the proinflammatory cytokine IL-17 is produced, which synergizes with IL-1 or TNF- α to destroy cartilage and bone.

Cytokines produced by macrophage-like synoviocytes, especially TNF- α , IL-1, and IL-6, dominate the RA synovium. Their production could be stimulated either by antigen-specific T cells or by T cells activated in an antigen-independent fashion by cytokines through receptors other than the TCR.

The synovium also contains Tregs that turn off the proinflammatory T cell-mediated responses; persistence of RA may represent a failure of this mechanism.

Angiogenesis and vasculogenesis in rheumatoid arthritis

■ ZOLTAN SZEKANECZ ■ EMESE BALOGH ■ ALISA E. KOCH

- Angiogenesis is the formation of new capillaries from preexisting vessels, whereas vasculogenesis is the generation of vessels from endothelial progenitor cells.
- The perpetuation of angiogenesis involving numerous soluble and cell surface-bound mediators has been associated with rheumatoid arthritis.
- Angiogenic mediators include growth factors, primarily vascular endothelial growth factor (VEGF), as well as proinflammatory cytokines, various chemokines, matrix components, cell adhesion molecules, proteases, and others.
- Among the several potential angiogenesis inhibitors, targeting of VEGF, hypoxia-inducible factor-1, angiogenic chemokines, tumor necrosis factor- α , and $\alpha_v\beta_3$ integrin may attenuate the action of angiogenic mediators and thus synovial angiogenesis.
- Vasculogenesis and the function of endothelial progenitor cells are impaired in rheumatoid arthritis but can be restored by the control of synovial inflammation.

INTRODUCTION

The formation of new capillaries from preexisting vessels, termed *angiogenesis*, is a key event underlying synovial inflammation, which perpetuates the recruitment of leukocytes into the synovium in rheumatoid arthritis (RA).¹⁻⁵ On the other hand, new vessel formation from endothelial progenitor cells (EPCs), termed *vasculogenesis*, is impaired in the inflammatory arthritides.⁶⁻⁸ This chapter reviews current issues regarding angiogenesis and vasculogenesis, the angiogenic process, its mediators and inhibitors, the most important regulatory networks, and finally the clinical relevance of angiogenesis and vasculogenesis in RA.

THE ANGIOGENIC PROCESS

Synovial angiogenesis consists of a cascade of multiple events. New capillaries develop from existing blood vessels. First, angiogenic mediators (described later) activate endothelial cells. This is associated with the production of proteases that degrade the basement membrane of the endothelium and the interstitium, thus enabling endothelial outgrowth. Migration of loose endothelial cells results in the formation of capillary sprouts. Endothelial cells in the midsection of the sprout undergo mitosis, whereas others at the tip of the sprout migrate only and do not proliferate. This step is followed by lumen formation within the sprout. Two sprouts then anastomose with each other to form capillary loops. New basement membrane is then synthesized. The continuous emigration of endothelial cells results in the development of second and further generations of new vessels. The outcome of angiogenesis is based on the imbalance between angiogenic mediators and angiostatic factors^{1,2,5,9,10} (Fig. 93.1 and Table 93.1).

Mediators of angiogenesis in rheumatoid arthritis

Several cytokines, growth factors, chemokines and their receptors, and certain cell adhesion molecules (CAMs), as well as other mediators, can modulate neovascularization in inflammation^{1-5,8} (see Table 93.1 and Fig. 93.1).

Among *growth factors*, vascular endothelial growth factor (VEGF) is of outstanding importance. VEGF directly induces angiogenesis and is also a

part of the hypoxia-hypoxia-inducible factor (HIF)-VEGF-angiopoietin (Ang) network discussed later in more detail. Among the isoforms VEGF-A to VEGF-E, VEGF-A may be the major regulator of angiogenesis. Other angiogenic mediators, such as interleukin-6 (IL-6), IL-17, IL-18, nitric oxide (NO), monocyte/macrophage migration inhibitory factor (MIF), endothelin 1 (ET-1), and others, may also act via VEGF-dependent or, in some, VEGF-independent mechanisms.^{2,11,12} Placenta growth factor (PlGF) is a member of the VEGF family, and this mediator also binds to the Flt-1/type 1 VEGF receptor (VEGFR1). PlGF is expressed abundantly in arthritic synovial tissue. Other growth factors, including fibroblast (FGF-1 and FGF-2), epidermal (EGF), hepatocyte (HGF), keratinocyte (KGF), insulin-like (IGF-1), connective tissue (CTGF), platelet-derived (PDGF), and transforming (TGF- β) growth factors, have been implicated in synovial angiogenesis. Many of these growth factors are bound to heparin and heparan sulfate proteoglycans in the synovial extracellular matrix (ECM), and they are mobilized by proteases during neovascularization.^{1-5,8}

Proinflammatory cytokines may exert direct angiogenic activity or may act indirectly via VEGF-dependent pathways. Among these mediators, tumor necrosis factor- α (TNF- α), IL-1, IL-6, IL-15, IL-17, IL-18, oncostatin M, MIF, and granulocyte (G-CSF) and granulocyte-macrophage (GM-CSF) colony-stimulating factors have been associated with synovial angiogenesis.^{2,5,13,14}

Numerous *chemokines* and *chemokine receptors* have been implicated in the angiogenesis underlying RA. The angiogenic nature of most CXC chemokines has been associated with the glutamyl-leucyl-arginyl (ELR) amino acid motif within their structure. The most relevant ELR-containing CXC chemokines that mediate angiogenesis include CXCL1 (GRO α), CXCL5 (ENA-78), CXCL7 (CTAP-III), and CXCL8 (IL-8).^{8,15-17} In contrast, ELR-lacking CXCL4 (PF4), CXCL9 (MIG), and CXCL10 (IP-10) inhibit angiogenesis. Some authors suggest that the effect of VEGF on endothelial cells may, in part, be mediated by CXCL10.¹⁸ CXCL12 (SDF-1) may play a significant role in RA-associated angiogenesis and synovial lymphoid neogenesis despite the fact that this chemokine lacks the ELR motif. Among CC chemokines, CCL2 (MCP-1) may induce endothelial cell chemotaxis *in vitro* and angiogenesis *in vivo*. CCL23 has been implicated in the migration of vascular endothelial cells and angiogenesis-associated matrix metalloproteinase (MMP) production. CX₃CL1 (fractalkine) is involved in both the angiogenesis and atherosclerosis underlying inflammatory rheumatic diseases. Among chemokine receptors, CXCR2 may be the most relevant one to ELR-containing angiogenic CXC chemokines, such as CXCL1, CXCL5, and CXCL8, on endothelial cells. CCR2-CCL2 and CCR7-CCL21 interactions are also involved in synovial neovascularization.^{18,19}

Several *ECM components*, *CAM*, and *proteases* have been implicated in the adhesive and angiogenic processes in RA. Type I collagen, fibronectin, laminin, vitronectin, tenascin, and proteoglycans mediate whereas thrombospondin-1 (TSP-1) inhibits endothelial cell adhesion and neovascularization. As described earlier, some growth factors bind to proteoglycans during angiogenesis. Among CAMs, most β_1 and β_3 integrins, E-selectin, the L-selectin ligand CD34, selectin-related glycoconjugates (including Lewis^x/H and MUC18), vascular cell adhesion molecule-1 (VCAM-1), platelet-endothelial cell adhesion molecule-1 (PECAM-1, CD31), endoglin, and junctional cell adhesion molecule A (JAM-A) and JAM-C are expressed on the endothelial surface and promote angiogenesis. $\alpha_v\beta_3$ Integrin seems to be of significant importance because this CAM is involved in osteoclast activation and subsequent development of erosions, as well as in synovial angiogenesis in RA. Focal adhesion kinases (FAKs) are involved in $\alpha_v\beta_3$ integrin signaling. FAKs have been detected in RA synovium, thus suggesting their role in synovial inflammation and angiogenesis. Other angiogenic factors, such as chemokines, may act via integrin-dependent pathways. MMPs, ADAM, and ADAMTS proteases digest the ECM, release growth

Fig. 93.1 Rheumatoid arthritis (RA) is associated with an abundance of angiogenic over angiostatic factors. Only the most important mediators and compounds are presented. DMARDs, disease-modifying antirheumatic drugs; ELR, glutamyl-leucyl-arginyl; HIF, hypoxia-inducible factor; VEGF, vascular endothelial growth factor.

TABLE 93.1
Some angiogenic and angiostatic factors in rheumatoid arthritis*

	Mediators	Inhibitors
Chemokines	CXCL1, CXCL5, CXCL7, CXCL8, CXCL12, CCL2, CCL21, CCL23, CX3CL1	CXCL4, CXCL9, CXCL10, CCL21
Matrix molecules	Type I collagen, fibronectin, laminin, heparin, heparan sulfate	Thrombospondin, RGD sequence
Cell adhesion molecules	β_1 and β_3 integrins, E-selectin, P-selectin, CD34, VCAM-1, endoglin, PECAM-1, VE-cadherin, Le ^x /H, MUC18	RGD sequence (integrin ligand)
Growth factors	VEGF, bFGF, aFGF, PDGF, EGF, IGF-1, HIF-1, TGF- $\beta^{\dagger}$	TGF- $\beta^{\dagger}$
Cytokines	TNF- α , IL-6, [†] IL-15, IL-18	IL-4, IL-6, [†] IFN- α , IFN- γ
Proteases	MMPs, plasminogen activators	TIMPs, plasminogen activator inhibitors
Others	Angiogenin, substance P, prolactin	Disease-modifying antirheumatic drugs, infliximab, etanercept, angiostatin, endostatin

*See text for abbreviations.

[†]Mediators with both proinflammatory and antiangiogenic effects.

factors and other angiogenic mediators, and thus promote inflammatory neovascularization.^{2,9,10,20-23}

Additional *angiogenic factors* relevant to RA include, without mentioning further details, serum amyloid A (SAA), ET-1, members of the cyclooxygenase-2 (COX-2)–prostaglandin E₂ network, angiogenin, angiotropin, pleiotrophin, platelet-activating factor (PAF), substance P, erythropoietin, adenosine, histamine, prolactin, thrombin, sphingosine-1-phosphate (S1P), and possibly many others.^{1-4,8,12}

Vasculogenesis in arthritis

EPCs are hematopoietic stem cells that express, among other antigens, CD34, CD133, type 2 VEGF receptor (Flk-1/VEGFR2), and the CXCR4 chemokine receptor. During vasculogenesis, EPCs differentiate into mature endothelial cells. Defective vasculogenesis as a result of impaired EPC numbers and function has been described in RA. Effective control of inflammation with corticosteroids and anti-TNF agents may stimulate EPCs and thus restore vasculogenesis. In addition, induction of vasculogenesis may also suppress premature atherosclerosis in RA.⁶⁻⁸

Regulatory networks in synovial angiogenesis

The *hypoxia-HIF-VEGF-Ang/Tie* system seems to be of outstanding importance in RA-associated angiogenesis (Fig. 93.2). VEGF is induced by

hypoxia and HIFs (HIF-1 and HIF-2) in RA. Significant hypoxia is characteristic of RA joints, and a stimulatory effect of hypoxia on the angiogenic drive of RA synovial fibroblasts has been demonstrated. Low oxygen tension in the joint has been associated with disease activity and increased expression of angiogenic VEGF. Hypoxia enables the outgrowth of immature, unstable vessels. HIFs are master regulators of the adaptive responses to hypoxia. HIF is a heterodimeric transcription factor composed of HIF- α and HIF- β . Among the three known HIF- α subunits, HIF-1 α and HIF-2 α are able to dimerize with HIF-1 β and thus bind to hypoxia-response elements (HREs). VEGF is a target gene for HIFs, and its gene contains HREs. High oxygen tension leads to hydroxylation and thus degradation of HIF- α , whereas hypoxia inhibits HIF hydroxylation, thereby allowing stabilization of HIF-1 α , dimerization with HIF-1 β , and initiation of the transcription of genes containing HREs (see Fig. 93.2). Both HIF-1 α and HIF-2 α are strongly expressed in RA synovium. However, hypoxia may also act via HIF-independent regulatory pathways, including the peroxisome proliferator-activated receptors (PPARs). The Ang1/Tie2 complex interacts with VEGF during the stabilization of newly formed blood vessels. In contrast, Ang2, an antagonist of Ang1, inhibits vessel maturation. Both Ang1 and Tie2, as well as VEGF, have been detected in RA synovium even in very early phases of the disease. Toll-like receptors such as TLR2 may also induce VEGF-dependent angiogenesis, and this is mediated through Tie2 signaling in RA. Survivin, an inhibitor of apoptosis, is likewise involved in VEGF-dependent angiogenesis. Hypoxia also stimulates the production of

Fig. 93.2 In a normoxic state, hypoxia inducible factor- α (HIF- α) is heavily hydroxylated, which leads to destabilization and degradation of HIF. In cases of hypoxia, HIF- α is dehydroxylated, translocates to the nucleus, and binds to HIF-1 β and the coactivator p300. This will result in binding of the HIF complex to hypoxia responsive elements (HREs) found in the gene for vascular endothelial growth factor (VEGF) and other angiogenic mediators.

CXCL12, a major angiogenic chemokine described earlier, by RA synovial fibroblasts.^{2,11,12,19,24-26}

Perspectives of angiogenesis targeting and restoration of vasculogenesis in arthritis

Angiogenesis can be inhibited by either blocking the action of angiogenic mediators or by using angiostatic compounds^{2,11,12,27,28} (see Table 93.1 and Fig. 93.1). Currently used antirheumatic agents such as rofecoxib, dexamethasone, chloroquine, sulfasalazine, methotrexate, azathioprine, cyclophosphamide, leflunomide, thalidomide, tacrolimus, minocycline, and anti-TNF biologics, apart from other important antiinflammatory effects, nonspecifically suppress angiogenesis, including VEGF and Ang1/Tie2.^{2,27,28}

VEGF inhibitors have been tried in patients with arthritis, as well as in cancer studies. These inhibitors may include antibodies to VEGF or VEGFRs, soluble VEGFR constructs, small-molecule VEGF and VEGFR inhibitors, or inhibitors of VEGF and VEGFR signaling. The VEGF tyrosine kinase inhibitor vatalanib (PTK787) and an anti-VEGFR1 antibody exerted significant angiostatic and antiarthritic effects in animal models of arthritis. A soluble VEGFR1 chimeric protein inhibited synovial endothelial proliferation. Soluble Fas ligand (sFasL, CD178) is a functional inhibitor of the 165-amino acid form of VEGF (VEGF165), and it inhibited angiogenesis in arthritis.^{2,4,11,12,27,28}

The involvement of PPARs in hypoxia-induced VEGF production was discussed earlier. The PPAR- γ ligands rosiglitazone and pioglitazone inhibited VEGF-induced angiogenesis.² HIFs may also be targeted in arthritis. For example, YC-1, a superoxide-sensitive stimulator of soluble guanylyl cyclase and an HIF-1 inhibitor, may potentially be used to suppress inflammatory angiogenesis.^{25,27} The benzophenone analogue BP-1, an HIF-1 α inhibitor, ameliorated adjuvant-induced arthritis (AIA) in rats. HIF-1 signaling has also been targeted in inflammatory bowel disease.^{2,25,27} As far as the Ang1/Tie2 system is concerned, a soluble Tie2 receptor transcript delivered via an adenoviral vector to mice attenuated the incidence and severity of collagen-induced arthritis (CIA).^{2,27} Very recently, an Ang2-targeting peptide was genetically fused to the anti-TNF antibody adalimumab. This novel bispecific antibody enhanced the efficacy of anti-TNF.²⁹

Regarding the targeting of other growth factors, imatinib mesylate, an inhibitor of PDGF receptor activation, inhibited synovial pannus formation in murine CIA. An anti-Flt-1/VEGFR1 hexapeptide, GNQWFI abrogated PlGF-induced angiogenesis, cytokine production, and the development of CIA in mice.^{2,27}

The anticytokine therapy currently used to treat arthritides may also influence angiogenesis. For example, TNF- α blockade by infliximab reduced

VEGF expression and vascularity in RA synovium. Infliximab also reduced synovial Ang1 and Tie2 expression. The anti-IL-6 receptor antibody tocilizumab also decreased serum levels of VEGF in RA.^{2,12,13}

The role of proteases in angiogenesis was described earlier. Numerous protease inhibitors, including tissue inhibitors of metalloproteinases (TIMPs) and plasminogen activator inhibitors (PAIs), which antagonize the effects of proteases, have been tried in angiogenesis models.^{2,27,30}

Antibiotic derivatives, including minocycline, fumagillin analogues, deoxyspergualin, roxithromycin, and clarithromycin, also inhibit the release of VEGF and other angiogenic mediators and thus neovascularization. The synthetic fumagillin derivatives TNP-470 and PPI-2458 inhibited VEGF and VEGF-dependent angiogenesis. Human RA trials have been conducted in which minocycline, roxithromycin, and clarithromycin were found to exert moderate, but significant clinical effects.^{1,2,27,28}

Among other inhibitors of angiogenic mediators, the ET-1 antagonists currently used for the treatment of pulmonary hypertension may also exert antiangiogenic effects.³¹ The microtubule destabilizer paclitaxel (Taxol), used in cancer therapy, also acts via HIF-1 α blockade. SIP is also angiogenic, and SIP inhibitors, such as fingolimod (FTY720), are in clinical trials for various autoimmune diseases. FTY720 also acts as an inhibitor of the FAKs described earlier. Chemical lead 2 (CL2, Edg-1) is a non-SIP analogue. CL2 inhibited tube formation in endothelial cultures, suppressed VEGF-induced angiogenesis, and attenuated arthritis in the CIA model.^{2,23,27,28} Very recently, peptides have been isolated from libraries of phages preferentially homing to the inflamed joints of AIA rats. Some of these peptides that bound to synovial endothelial cells were able to inhibit arthritis, as well as VEGF signaling and angiogenesis.²⁹

Recently, an emerging number of compounds in traditional Chinese and Korean medicine have been implicated in angiogenesis. Among these compounds, scopolin (a coumarin derivative found in *Erycibe obtusifolia* Benth), celastrol (an active ingredient of *Tripterygium wilfordii*, also known as the "Thunder God vine"), or fisetin (the active ingredient of *Rhus verniciflua* Stokes) may also have angiostatic effects in arthritis.²

Apart from inhibition of angiogenesis, endogenously produced angiostatic compounds, such as VEGF, HIFs, or $\alpha_v\beta_3$ integrin, also block the action of angiogenic mediators and thus indirectly suppress neovascularization. Some of these compounds have already been used in an attempt to target tumor- or inflammation-associated neovascularization. Angiostatic cytokines include interferon- α (IFN- α), IFN- γ , IL-4, IL-12, and leukemia inhibitory factor (LIF). These cytokines inhibit the release of VEGF and other angiogenic mediators. IL-4 and IL-13 gene transfer inhibited synovial angiogenesis in rats. Angiostatic CXC chemokines that lack the ELR motif include CXCL4 (PF4), CXCL9 (MIG), and CXCL10 (IP-10),¹⁸ CCL21 (SLC) is an

angiostatic CC chemokine that inhibits tumor progression. *Angiostatin* (a fragment of plasminogen), *endostatin* (a fragment of type XIII collagen), and their derivatives block $\alpha_v\beta_3$ integrin-dependent angiogenesis. *Type IV collagen derivatives*, including arrestin, canstatin, and tumstatin, also inhibit neovascularization. *2-Methoxyestradiol (2-ME)*, a natural metabolite of estrogen, inhibits angiogenesis by disrupting microtubules and by suppressing HIF-1 α activity.^{13,14,18,19,27,28}

As discussed earlier, corticosteroids and anti-TNF agents may stimulate EPCs and thus *restore vasculogenesis* in RA. The CXCL12 (SDF-1) inhibitor bicyclam (AMD3100) mobilized EPCs in mice. Because the number of EPCs correlates with improvement in the 28-joint disease activity score (DAS28) in RA, suppression of systemic inflammation and disease activity by any means would improve vasculogenesis.^{7,8}

SUMMARY

This chapter discussed the pathogenic role of angiogenesis and vasculogenesis in RA. A number of soluble and cell-bound factors may stimulate or inhibit angiogenesis. The outcome of such “angiogenic diseases” depends highly on the imbalance between angiogenic and angiostatic mediators. Impaired EPC function and vasculogenesis have been associated with RA. Several attempts have been made to therapeutically interfere with the cellular and molecular mechanisms described in this chapter. Specific targeting of abundant synovial angiogenesis, as well as restoration of defective vasculogenesis, may be useful for the future management of RA.

The rheumatoid joint: synovitis and tissue destruction

■ ELLEN M. GRAVALLESE ■ PAUL A. MONACH

- Synovial tissue in joints with rheumatoid arthritis (RA) is markedly expanded by the recruitment and retention of inflammatory cells along with the formation of villous projections and the generation of pannus tissue that invades and destroys cartilage and bone.
- The pathogenic events in RA probably occur in stages, and mechanisms leading to initiation of the disease appear to be distinct from those involved in the perpetuation of inflammation and eventual destruction of joint tissue.
- Chronic synovitis is maintained by the interactions of cell types native to the joint and inflammatory cells recruited to the joint, with the subsequent establishment of cytokine "networks."
- Cartilage destruction results from the production of enzymes that destroy components of the cartilage extracellular matrix by cells within synovial tissue and by chondrocytes; osteoclasts contribute to the destruction of articular bone.

INTRODUCTION

Inflammation of joints lined by synovium (synovitis) is the hallmark of rheumatoid arthritis (RA). Associated with synovitis is a propensity to destroy articular cartilage and bone, the structural components of the joint. Consequently, joint tissue from patients with RA has been the subject of extensive research, which has led to tremendous advances in our understanding of the pathogenesis of synovitis and the subsequent rational development of effective new therapies. This chapter reviews the pathologic changes seen in RA synovium, followed by a detailed summary of the phenotypic and functional changes that occur in synovitis in RA, including the cell types and inflammatory mediators responsible for establishing and maintaining chronic inflammation. Mechanisms of joint destruction are reviewed. Finally, this information is synthesized into a proposed model of pathogenesis that integrates knowledge gained from the study of synovial tissue, animal models of arthritis, and insight from clinical trials.

NORMAL SYNOVIUM

In a normal joint the synovium is a thin membrane derived from cells of the embryonic mesenchyme that lines the fibrous joint capsule (Fig. 94.1). The synovium and joint capsule attach to skeletal tissue at the interface of cartilage and bone, and normal synovial tissue does not encroach on articular cartilage. The structural features of normal synovium are covered in detail in Chapter 4, and thus only a brief summary is included here.

The most superficial layer of the synovium, lying adjacent to the joint cavity, is known as the synovial intima or synovial lining cell layer. Electron microscopic (EM) images have demonstrated that the cells within this layer are loosely adherent to the synovial subintimal or sublining tissues and that these cells form a discontinuous layer lacking a true basement membrane.¹ Cells within the synovial lining layer are 6 to 12 μ m in diameter, excluding the numerous finger-like projections extending from the cell surface. Two distinct populations of cells have been identified on EM images: type A or macrophage-like synoviocytes and type B or fibroblast-like synoviocytes (FLSs). Type A synoviocytes contain filopodia, a prominent Golgi apparatus, lysosomes, and vacuoles.¹ These cells have a sparse endoplasmic reticulum because they are primarily phagocytic cells that are presumably present in the joint to clear particulate matter from the joint cavity. In addition, they

express receptors for the Fc domains of IgG. In contrast, type B synoviocytes are fibroblast-like cells that contain abundant machinery for protein synthesis and fewer filopodia and vacuoles and lack Fc receptors (Fig. 94.2).¹ These cells can be distinguished by surface marker expression using immunohistochemical techniques (Fig. 94.3).

SYNOVIUM IN RHEUMATOID ARTHRITIS

In RA, chronic, clinically significant synovial inflammation develops and eventually leads to destruction of cartilage and bone. At the gross level, the inflamed synovial tissue in RA demonstrates marked expansion, with the synovial surface thrown into innumerable hyperemic and edematous villous projections that extend into the joint cavity. The microscopic changes seen in the synovium of patients with RA are not unique to this disease and can occur in other inflammatory arthritides. However, certain characteristic histologic findings can support the clinical diagnosis, including hyperplasia of the synovial lining layer, a mixed inflammatory cell infiltrate in the subsynovium with follicle and germinal center formation in some cases, neovascularization, and in clinically active disease, deposition of fibrin (Fig. 94.4).

In RA the synovial lining layer may be up to 12 cells in thickness, and individual cells may appear hypertrophic. Much of this increase is due to recruitment of cells of the monocyte-macrophage lineage from bone marrow. Evidence for recruitment of these cells into normal synovial tissue comes from studies of radiation chimeras of normal and beige mice. In beige mice, giant secondary lysosomes are present in cells of the monocyte-macrophage lineage. After bone marrow cells from beige mice were engrafted into normal irradiated histocompatible recipient mice, giant granules were identified in up to 7% of type A synovial lining cells.² Because macrophages are present in the sublining as tissue macrophages, as well as in the lining as type A synoviocytes, it is not entirely clear whether the greatly increased number seen in rheumatoid synovial tissue arises from division of local precursors or differentiation from newly recruited blood monocytes, but the latter mechanism is presumed to be the major source. The degree to which *in situ* division of resident cells in synovial tissue occurs and contributes to hyperplasia of the lining layer is still a matter of debate, but markers of cell proliferation, including proliferating cell nuclear antigen, have been identified in type B synoviocytes in the lining layer, thus demonstrating that some cell division does occur.³ The increase in the number of synovial lining cells in RA is significant because these cells are a source of a panoply of cytokines and other inflammatory mediators that contribute to chronic inflammation, as well as a source of matrix-degrading enzymes.

The inflammatory infiltrate within synovium in patients with established RA is heterogeneous and composed of T and B cells, plasma cells, and macrophages, as well as a lesser number of dendritic cells (DCs), mast cells, natural killer (NK) cells, and occasionally, neutrophils. Neutrophils are more commonly seen in synovial fluid but can be present in significant number in synovial tissue during an acute flare of disease. Most studies demonstrate a predominance of CD4+ over CD8+ T cells, with CD4+ cells being present diffusely, in aggregates, and in perivascular areas. B cells are also present diffusely and in aggregates, and immunoglobulin-producing plasma cells, some of which synthesize rheumatoid factor (RF), are the predominant infiltrating cells in some cases. Macrophages are usually present in significant number between and sometimes within lymphoid aggregates. Although macrophages may act as antigen-presenting cells to resident T cells, DCs, which are more potent antigen-presenting cells, have also been shown to interdigitate among T-cell aggregates. In addition, resident B cells may also serve as antigen-presenting cells, particularly for antigens internalized via their surface immunoglobulin receptors.

Fig. 94.1 Low-power view of normal synovial tissue. The intimal lining shown at the top of this section is only one or two cell layers deep, and sublining blood vessels and mononuclear cells are sparse.

Fig. 94.2 Features of type A (macrophage-like) and type B (fibroblast-like) synoviocytes are shown.

A definite heterogeneity of histologic findings is seen in patients with RA. However, distinct patterns of cellular infiltration take place and have only recently been categorized. Although cells within the synovium can move through tissue in a dynamic fashion, synovial tissue from patients with RA typically has one of three histologic patterns of inflammatory cell infiltration, and these patterns appear to be preserved over time. Furthermore, these patterns of inflammation have been associated with typical and distinct cytokine profiles and may therefore have clinical relevance.⁴

The most common histologic pattern is a diffuse inflammatory infiltrate in which infiltrating immune cells, predominantly lymphocytes and macrophages, are interspersed in a haphazard manner among resident synovial fibroblasts and blood vessels. This form of synovitis is associated with low levels of messenger RNA (mRNA) for interferon- γ (IFN- γ) and interleukin-4 (IL-4), as well as low levels of tumor necrosis factor (TNF) and IL-1 β mRNA. In addition, patients with this form of synovitis tend to have clinically milder disease. A second pattern is follicle formation in which infiltrating T and B cells are arranged in distinct follicles or aggregates. In some cases these follicles become highly organized into true, functionally competent germinal centers similar to those present in lymph nodes.⁵ Finally, in the rarest form of synovitis, which occurs in only a small percentage of cases, a granulomatous inflammatory infiltrate is seen in which granulomas resembling rheumatoid nodules are present within synovial tissue. Both IFN- γ and IL-4 mRNA is characteristically produced in this form of synovitis, as are high levels of TNF and IL-1 β , thus suggesting that these tissues are associated with significant T-cell and macrophage stimulation. Patients with granulomas in synovial tissue also typically have rheumatoid nodules in their skin.⁴

Fig. 94.3 Immunohistochemical staining of rheumatoid synovium. (a) Staining (brown) for CD55 demonstrates type B (fibroblast-like) synoviocytes in the lining layer. (b) Staining (red) for CD14 demonstrates type A (macrophage-like) synoviocytes in the lining layer, as well as macrophages in the sublining tissue.

MECHANISMS OF CHRONIC SYNOVITIS IN RHEUMATOID ARTHRITIS

Mechanisms for the recruitment and retention of inflammatory cells in chronic inflammatory diseases, including RA, have been the subject of intense investigation in recent years. The influx of inflammatory cells into synovial tissue occurs primarily through tethering of cells via selectins; upregulation of adhesion molecules, including vascular cell adhesion molecule-1 (VCAM-1), intercellular adhesion molecule-1 (ICAM-1), ICAM-2, and others on postcapillary venules; and chemokine-chemokine receptor interactions, which act as cellular “homing signals.” The proinflammatory cytokines produced within RA synovial tissue, including TNF and others, can induce the expression of several adhesion molecules on vascular endothelium.

Once inflammatory cells have served their purpose at a site of injury, these cells are normally cleared via apoptosis or emigration from the site. In RA, however, chronic inflammation persists because of an imbalance between cell recruitment, proliferation, and retention on the one hand and cell death and emigration from the tissue on the other hand. In the case of RA, interactions between T cells and stromal cells in synovial tissue favor

Fig. 94.4 Histologic evaluation of the synovium in chronic rheumatoid arthritis demonstrates hyperplasia of the synovial lining layer, infiltration of a heterogeneous admixture of mononuclear cells, including lymphocytes and plasma cells in the sublining tissue, and numerous blood vessels.

inhibition of T-cell apoptosis⁶ via the expression of IFN- β by resident synovial macrophages and fibroblasts. T-cell retention is also probably favored through upregulation of the chemokine receptor CXCR4 on T cells, which is induced by locally expressed transforming growth factor- β (TGF- β). The ligand for CXCR4, stromal cell-derived factor-1 (SDF-1 or CXCL12), is expressed on synovial cells and upregulated on RA as compared with osteoarthritis (OA) synovial fibroblasts. Blockade of the interaction between these factors has been demonstrated to decrease the clinical severity of arthritis in an experimental model.⁷

Pannus

A characteristic histologic feature seen in patients with RA is the presence of a distinctive tissue located at the interface between synovium and cartilage/bone at sites of joint destruction. This tissue is known as *pannus*, which is Latin for “cloth” or “covering.” Pannus tissue, not seen in this exact form in other inflammatory or noninflammatory arthritides, was so named because of its location—draped over cartilaginous surfaces and adherent to these surfaces. It is derived from the synovial membrane and is thought to mediate the process of tissue destruction. EM studies of the cellular composition of pannus have demonstrated that fibroblast-like cells predominate in this tissue, especially on the surface, but that in deeper layers and admixed with fibroblasts are cells with the EM appearance of macrophages.⁸ Pannus tissue has fewer lymphocytes and other inflammatory cells than synovial tissue remote from bone does, although such cells are often present (Fig. 94.5).

COMPONENTS OF RHEUMATOID SYNOVIUM

Cells of rheumatoid synovium

Macrophages

Macrophages are abundant in rheumatoid synovium and are readily identified in tissue sections or after dispersion of tissue into cell suspensions by their morphology and by surface markers such as CD14 and CD68. The number of macrophages noted in biopsy specimens correlates with risk for radiographic joint destruction.⁹ Although heterogeneity is undoubtedly present, cells of this lineage in rheumatoid synovium and synovial fluid show evidence of activation, such as surface markers characteristic of mature phagocytic cells and high levels of major histocompatibility complex (MHC) class II molecules important for the presentation of peptide antigens to CD4+ T cells.

Macrophages within the lining layer appear to differ from those in the sublining in their expression of adhesion molecules and secreted mediators.⁹ By analysis of tissue sections or freshly dispersed synovium, macrophages,

Fig. 94.5 Histology of the pannus-bone interface. (a) Low-power view demonstrating invasion of pannus tissue into cartilage and bone. (b) High-power detail demonstrating multinucleated osteoclast-like cells at the interface of pannus and bone.

especially those in the lining layer, appear to be a major source of numerous cytokines, including two known to be critically involved in the pathophysiology of RA, TNF and IL-1,¹⁰⁻¹³ as well as other cytokines that have well-described effects on immune and inflammatory responses, either stimulatory (IL-6, IL-12, IL-15, granulocyte-macrophage colony-stimulating factor [GM-CSF]) or inhibitory (IL-1 receptor antagonist [IL-1Ra], TGF- β).^{10,11,14,15} Many cell-surface receptors influence the activity of macrophages. Notable examples expressed on synovial macrophages *in vivo* include the p55 and p75 TNF receptors, the low-affinity IgG receptors Fc γ RII and Fc γ RIII, and the adhesion molecules CD31 and CD44. Investigation is ongoing into the expression by synovial macrophages of more recently described inflammatory mediators and receptors, such as the ligand-receptor pair of high mobility group box 1 (HMGB1) chromosomal protein and the receptor for advanced glycation end products, Toll-like receptors (TLRs) for microbial products, novel interleukins, and novel members of the TNF superfamily, including B-lymphocyte stimulator (BLyS).

Although macrophages have the machinery to participate importantly in the synthesis of lipid mediators of inflammation, destruction of cartilage and bone, and antigen presentation to T cells, it is unclear how their contribution to these activities compares with that of FLSs (for the former two functions) or that of DCs and B cells (for the latter). Macrophage cell lines

derived from synovial tissue have been relatively difficult to obtain. Instead, macrophages derived from synovial fluid or from peripheral blood monocytes have been studied *in vitro* to determine the effects of various mediators on macrophage expression of cell-surface molecules, proinflammatory cytokines, and effector functions.¹⁶ At a level of great simplification, cytokines that stimulate macrophages include TNF, IL-1, IL-15, IL-17, and IL-18, and suppressive cytokines include IL-1Ra, IL-4, IL-10, IL-11, and IL-13.^{16,17} Macrophages are also stimulated by cell-surface molecules on activated T cells, even if those T cells have been killed.¹⁸

Fibroblast-like synoviocytes

Like type A synoviocytes, type B synoviocytes, or FLSs, are greatly expanded in number in rheumatoid synovium, although type A cells remain more abundant. FLSs in normal synovial lining differ from fibroblasts in the sub-lining and other tissues, most notably by the expression of VCAM-1, cadherin-11, and the intracellular enzyme uridine diphosphate glucose 6-dehydrogenase (UDPGD).^{19,20} Rheumatoid FLSs are notable for their ability to produce enzymes with the capacity to degrade cartilage (see later in the section "Joint Destruction"). Other pathologic functions that have been ascribed to FLSs include differentiation into follicular DCs, which organize germinal centers for B-cell maturation,²¹ and an ability to present superantigens (bacterial proteins that bind MHC and the T-cell receptor [TCR] outside the usual interface), but not necessarily conventional peptide antigens, to T cells.²²

FLSs are strikingly active within the innate immune system based on responsiveness to and secretion of various cytokines and other mediators. IL-1 and TNF appear to be the major stimulators of FLSs and have been used in many *in vitro* studies; receptors for these cytokines are also detectable on FLSs in tissue sections.^{13,23} Bacterial products such as lipopolysaccharide (LPS) and peptidoglycan are also stimulatory, presumably through specific receptors such as TLR4 and TLR2, respectively. Under such stimulation, FLSs secrete IL-6, the related cytokine IL-11, and numerous chemotactic cytokines (chemokines) capable of acting on a variety of hematopoietic cell types.^{24,25} Some of these products are also produced at detectable levels without exogenous stimulation. Some evidence indicated that FLSs are the predominant source of other mediators such as IL-16 and nitric oxide.

The concept of rheumatoid pannus as a benign tumor has been discussed for many years, with a focus on the FLS as a "partially transformed" cell. Rheumatoid FLSs indeed share many features of transformed cells, such as anchorage-independent growth *in vitro* and expression of proto-oncogenes and telomerase. Genetic analysis of individual cells suggests division of FLSs or precursor clones in erosive pannus.²⁶ However, these features are characteristic of not only premalignant cells but also otherwise normal cells that have the potential to divide and are not terminally differentiated. Despite evidence of genetic instability in FLSs based on the loss or duplication of chromosomal markers, this is equally true of FLSs derived from patients with OA or RA.²⁷ Thus, although FLSs in RA do have durable phenotypic changes based on their growth properties *in vitro*, as well as on their ability to degrade cartilage *in vivo* when cotransplanted with normal cartilage into mice with severe combined immunodeficiency (SCID),²⁸ use of the terms *benign tumor* and *partially transformed* suggests a potential that remains unsubstantiated.

B cells

The prevalence and distribution of B cells are two of the most variable features of rheumatoid synovium. Circulating autoantibodies are characteristic of RA but are of uncertain pathologic significance. Studies of B cells in rheumatoid synovium have therefore focused heavily on local production of autoantibodies and evidence for local maturation of antibody-producing cells. B cells have other functions, including presentation of antigens to CD4+ T cells and secretion of cytokines, but the importance of such functions in RA is unclear.

Sequencing of the immunoglobulin genes expressed in RA synovium has suggested that local clonal expansion of B cells takes place, but recent studies have questioned whether the lymphoid follicles and germinal centers seen in some rheumatoid synovium promote the maturation and expansion of antigen-specific B cells as they do in lymphoid organs.²⁹ Determination of which antigens might be recognized by synovial B cells has been approached in four ways. First, levels of specific autoantibodies in synovial tissue and fluid have been compared with those in blood from the same patients. Levels of RF and anti-citrullinated peptide antibodies (ACPAs) are locally enriched according to these studies,^{30,31} which are quantitative but do not distinguish between local synthesis and local deposition. Second, synthesis of antibodies has been measured in tissue explants with use of biosynthetic labeling or inhibition of protein synthesis to differentiate between local synthesis and deposition. Rheumatoid synovium synthesizes

a large amount of IgG, IgM, and IgA, comparable to that produced by explanted lymphoid organs. Synovial B cells produce RF of all three of these isotypes and in higher relative concentrations than do peripheral blood B cells from RA patients.³²

Third, the ability of individual synovial B cells to produce antibodies of particular specificity has been assessed by plaque-forming cell and enzyme-linked immunosorbent spot (ELISpot) assays. Large numbers of B cells secreting antibodies to type II collagen and C1q have been detected in the majority of synovial tissue from both RF-seropositive and RF-seronegative patients.³³ Notably, none of these patients had detectable circulating antibodies to these autoantigens. Fourth and finally, hybridomas have been made from synovial B cells, and the monoclonal antibodies produced by these cells have been evaluated for binding to antigens. Cells making antibodies to cartilage oligomeric matrix protein, the bacterial heat shock protein hsp60, and several other proteins have thus been identified.³⁴ This apparent diversity of local autoantibodies makes it clear that evaluation of serum may greatly underestimate synovial levels of potentially pathogenic antibodies.

T cells

T cells are the dominant lymphocytes infiltrating rheumatoid joints, and CD4+ cells predominate over CD8+ cells in most RA patients, as is true in lymph nodes and blood. A key role of CD4+ T cells in the pathogenesis of RA is suggested by the strong genetic linkage of disease susceptibility to HLA-DR alleles. However, various findings regarding synovial T cells have led to disagreement about their role in chronic disease, as discussed later in this chapter.

Many synovial T cells express surface markers suggesting prior activation, such as particular CD45 isoforms, CD44, and MHC class II molecules.³⁵ No clear evidence has demonstrated that activation occurs locally despite the various potential antigen-presenting cells in inflamed synovium. Previously activated T cells home nonspecifically to inflamed sites by virtue of their expression of particular adhesion molecules. Therefore, previously activated T cells are likely to be recruited into the synovium from peripheral blood independent of their antigen specificity.

Despite expression of activation markers, T cells from RA patients are paradoxically hyporesponsive to further stimulation through the TCR *in vitro*. First described in circulating cells, this observation has been extended to cells from synovial fluid and tissue.³⁶ Synovial T cells have decreased levels of the ζ chain of the TCR, a key element in antigen-driven signaling³⁷; this abnormality has also been found in systemic lupus erythematosus and other chronic inflammatory states, as well as in an animal model of chronic infection, thus suggesting that it is a generic response to chronic immune stimulation. Other defects in intracellular signaling and cell-surface phenotype characterize synovial T cells, but whether these changes are all part of a single differentiation program is unknown. Strikingly, at least some of these defects can be produced by chronic stimulation of normal T cells *in vitro* with TNF.³⁷

Once immunologic studies had defined subsets of CD4+ T cells that secrete distinct panels of cytokines, often falling into the patterns of type 1 helper T (Th1) cells (expressing IL-2, IFN- γ , lymphotoxin- α [LT- α]) and Th2 cells (expressing IL-4, IL-5, IL-10, and IL-13), it became important to determine the expression of specific cytokines by T cells in rheumatoid synovium because these cytokine panels have very different influences on immune responses. The salient finding in these studies is the dearth of T cell-derived cytokines (Table 94.1), whether measured by *in situ* hybridization or immunostaining of tissue sections^{38,39} or by Northern blot or polymerase chain reaction of either whole synovium¹⁴ or T cells isolated from synovium.⁴⁰ Low numbers of cells staining for IFN- γ are found in both early (<1 year) and late (>5 years) RA.³⁸ Nevertheless, cytokine-producing T cells are present in synovial tissue and were originally reported to demonstrate a Th1 pattern of cytokine expression, but with some deviation from that paradigm. Thus, IFN- γ and LT- α are expressed and IL-4 is not^{39,40}; however, IL-2, a product of Th1 cells, is not found, whereas IL-10, a product of Th2 cells, is expressed.⁴⁰ Expression of the chemokine receptors CCR5 and CXCR3, which are associated with the Th1 phenotype, by the majority of synovial T cells also suggested Th1 dominance,⁴¹ and discordant results were obtained regarding production of IL-6 by synovial T cells.

The paradigm of predominance of Th1 over Th2 cells in rheumatoid synovium has been challenged by the more recent discovery of a new CD4+ effector helper T-cell subset, the Th17 cell.⁴² Th17 cells express IL-17A and IL-17F, along with IL-6, TNF, GM-CSF, and other cytokines. Much of the work in defining the Th17 cell has been performed in mice, in which this subset is most clearly distinguished from Th1 and Th2 cells. Th17 cells have also been identified in humans, although the cytokine expression pattern of human Th17 cells is somewhat less distinct than that of other helper T-cell

TABLE 94.1

Cytokines that have been intensively studied in rheumatoid arthritis*

	Proinflammatory/ antiinflammatory [†]	Increased in RA? [‡]	Clinical trial support [§]	Cytokine cellular sources	Salient effects, stimulatory [¶]	Salient effects, inhibitory [¶]
TNF	Pro	+	+	Mφ , many others	COX, IL-1, TNF, IL-6, chemo, MMP	
IL-1	Pro	+	+	Mφ , many others	COX, TNF, IL-6, chemo, MMP, endo	Proteoglycans
IL-2	Pro	—		Th1	T-cell proliferation, NK	
IL-4	Anti	—		Th2	Abs	IL-1, TNF
IL-6	Pro/anti	+	+	Mφ , FLS, chond	Abs, acute phase, FLS proliferation	IL-1, TNF, chemo
IL-10	Anti	+	—	Mφ , Th2, B	Abs	IL-1, TNF, chemo, COX, MMPs
IL-11	Anti	±		FLS	Acute phase	IL-1, TNF
IL-13	Anti	±		Th2		IL-1, TNF, COX
IL-15	Pro	+		Mφ , FLS, endo	T-cell proliferation, TNF, chemo	
IL-17	Pro	+		Th17	COX, chemo, osteoclasts	
IL-18	Pro	+		Mφ, FLS, chond	TNF, Th1	
IFN-α/β	Pro/anti	NR		DC		
IFN-γ	Pro/anti	±	±	Th1, NK	TNF	IL-1, COX, MMPs
GM-CSF	Pro	+		Mφ, many others	Nφ/Mφ differentiation/activation

Chemokines	Pro	+		Mφ, FLS , endo, others	Leukocyte chemotaxis	
RANKL		+		T, FLS, osteoblasts	Osteoclasts	

*Antagonists such as interleukin-1 receptor antagonist and soluble (decoy) receptors are not shown.

[†]Predominant effect of the cytokine.[‡]Increased (+) or not (—) versus osteoarthritis or normal synovium. ±, small differences or conflicting results; NR, not reported.[§]Importance established (+ or —) by clinical trials involving the cytokine itself (e.g., IL-10, IFN-α/β) or an agent that blocks its activity (e.g., TNF, IL-1, IL-6, IFN-γ). ±, uncertain result.^{||}Major sources of factors clearly upregulated in RA synovium are indicated in **bold**. B, B lymphocyte; chond, chondrocyte; DC, dendritic cell; endo, vascular endothelial cell; FLS, fibroblast-like synovial cell; Mφ, macrophage; NK, natural killer cell; Th1, Th2, subsets of CD4+ helper T cells.[¶]Stimulatory or inhibitory for production of the factors or activity of the cells listed. Abs, antibodies; chemo, chemokines; COX, cyclooxygenase-2 enzyme; Nφ, neutrophils.

ECM, extracellular matrix; GM-CSF, granulocyte-macrophage colony-stimulating factor; IFN, interferon; IL-1, interleukin; M-CSF, macrophage colony-stimulating factor; MMPs, matrix metalloproteinases; RANKL, receptor activator of nuclear factor κB ligand.

subsets. Differentiation factors for Th17 cells in mice (predominantly TGF-β and IL-6) also differ from those in humans (IL-1β and IL-23).⁴³

Regulatory T cells (Tregs) are a recently defined subset of T cells that are important for prevention of autoimmune disease and control of inflammation via secretion of IL-10 and TGF-β and also by mechanisms dependent on cell-cell contact.⁴⁴ The transcription factor Foxp3 is the most specific marker for Tregs, but they also express high levels of CD25, which has been used more frequently because of greater ease of detection. Data obtained by quantifying or manipulating cells using CD25 carry the caveat that this marker is also expressed on activated T cells at a somewhat lower level. Reports differ regarding whether Tregs circulate at higher levels in patients with RA than in healthy controls, but higher numbers have consistently been found in synovial fluid than in blood.⁴⁵ However, the *in vitro* suppressive function of circulating Tregs from RA patients is reduced by a mechanism dependent on TNF because suppressive function is restored by anti-TNF therapy⁴⁶ and addition of TNF to Tregs from healthy donors reduces suppressive activity.⁴⁷

The interaction of human T cells with other cell types infiltrating inflamed tissues, most notably monocytes/macrophages, has been studied *in vitro*. Work on co-cultures of normal human T cells and monocytes has shown that previously activated T cells induce the production of monocyte mediators such as IL-1, TNF, IL-10, and matrix metalloproteinases (MMPs) and that such induction involves both contact-dependent and contact-independent signals.⁴⁸ Effects on monocytes differ depending on whether the T cells are activated by stimulation through the TCR or by incubation with cytokines. Cytokine-activated T cells stimulate the release, from monocytes/macrophages, of TNF but not IL-10, whereas TCR-activated T cells stimulate the production of both cytokines.⁴⁸ Most interestingly, T cells freshly isolated from rheumatoid synovium behave like cytokine-stimulated and unlike TCR-stimulated T cells in this assay,⁴⁹ which has helped bolster the provocative hypothesis that antigen-specific T-cell activation is of little relevance in established RA.

Indeed, evidence for local expansion of antigen-specific T cells within the synovium has been difficult to obtain. Synovial T cells have been

described that react to peptides derived from the bacterial heat shock protein dnaJ⁵⁰ and to peptides from the matrix protein gp39,⁵¹ but in general, the search for autoreactive T cells has not been as fruitful as that for autoantibodies. Indirect evidence of skewed recruitment or local expansion of T cells has been sought by comparing TCR variable-region gene use in synovial and peripheral blood T cells in RA patients and controls, with the results summarized in a thorough review as being “notable for their contradictory and confusing nature.”³⁵

Despite these results, it is important to note that even in known antigen-driven responses, the percentage of antigen-specific T cells within an inflammatory lesion is quite low because of the nonspecific homing of previously activated cells to inflammatory sites, and the techniques used thus far may simply not be sensitive enough to detect an adaptive immune response, even one that is functionally important. Because previously activated T cells home nonspecifically to inflamed sites, the discovery of reactivity to common pathogens within inflamed tissue such as RA synovium must also be interpreted cautiously.

Neutrophils

Neutrophils are the predominant cell type in rheumatoid synovial fluid but are present only sparsely in inflamed synovium and pannus, although they have been located by EM studies at the cartilage-pannus junction.⁵² Neutrophils can, however, predominate in synovial tissue early in an acute flare of RA, and the histopathologic characteristics of a synovial biopsy specimen taken at this time may resemble those of a septic joint. Many synovial fluid neutrophils express surface markers indicative of activation by cytokines, such as the high-affinity IgG receptor FcγRI, the complement receptor CR3, and lactoferrin. In addition, synovial fluid contains antimicrobial peptides thought to be derived specifically from neutrophil granules.⁵³ There is little reason to propose that activation of neutrophils in rheumatoid joints differs from that in other inflamed but uninfected sites. Likewise, interaction of circulating neutrophils with endothelial cells in the joint is thought to use the same set of adhesion molecules as in other sites. Initial tethering and rolling are mediated by selectins (L-selectin on neutrophils, E-selectin on

endothelial cells) interacting with receptors containing sialyl-Lewis^x carbohydrate moieties. Tight adhesion is mediated by interaction of the β_2 integrins on neutrophils (LFA-1/CD11aCD18 and Mac-1/CD11bCD18) with ICAM-1 and ICAM-2 on endothelium.⁵⁴ Neutrophils do not express the integrin VLA-4, which may explain why they do not remain in synovial tissue, where expression of its counterreceptor VCAM-1 appears to be important in the retention of other kinds of leukocytes.

Details about the chemotaxis and activation of neutrophils have been gleaned from analysis of normal peripheral blood neutrophils cultured *in vitro*. IL-8/CXCL8, other ligands for the chemokine receptors CXCR1 and CXCR2, and TGF- β have been identified as important chemotactic factors for neutrophils.⁵⁴ Normal neutrophils can be induced to express many cytokines and chemokines *in vitro*, including IL-1 β and IL-8. In turn, IL-1 and IL-8 induce neutrophil effector functions such as degranulation, phagocytosis, and the respiratory burst.⁵⁴ In the case of IL-8, these effects are likely to be direct, but the priming of neutrophil functions by IL-1, more prominently seen *in vivo* than *in vitro*, is probably secondary to upregulation of the adhesion molecules E-selectin and ICAM-1 on endothelium⁵⁴ rather than a direct effect of IL-1 on neutrophils.

Dendritic cells

DCs, the cells most potent at presenting peptide antigens to T cells, are derived from precursors that migrate into joints and other tissues from peripheral blood. DCs make up 1% to 5% of the cells in rheumatoid synovial fluid⁵⁵ and can be isolated from synovial tissue as well. DCs can be distinguished from monocyte-derived cells by differences in surface markers, such as lower levels of CD14,⁵⁶ and the absence of phagocytic capacity. Synovial DCs express the co-stimulatory molecule CD40 and high levels of MHC class I and II molecules,⁵⁶ although divergent results have been obtained for expression of the co-stimulatory molecule CD80/B7-1.^{56,57} Thus, like other leukocytes in inflamed synovium, DCs appear to be activated. Considering the two predominant DC subtypes, the ratio of myeloid to plasmacytoid DCs is higher in RA than in non-RA synovium.⁵⁸ The role of DCs in initiating and perpetuating RA through the presentation of antigen to synovial T cells is a point of ongoing investigation and debate.

Mast cells

Mast cells are found in small numbers in rheumatoid synovium but perhaps at an increased density in comparison to normal tissue.⁵⁹ Interest in a potential role for mast cells in RA has been aroused by their importance in a mouse model of IgG-mediated inflammatory arthritis⁶⁰ and by their ability to secrete tryptases and other proteases, preformed cytokines, and vasoactive and chemotactic factors. It is possible that mast cell phenotypes are more diverse and tissue specific than the classic delineation of connective tissue and mucosal subtypes. For example, mast cells in RA synovium differ from those in normal or OA synovium in their expression of surface markers, such as corticotropin-releasing hormone receptor 1 and the chemokine receptor CXCR3.

Chondrocytes and endothelial cells

In addition to their complex structural role in cartilage, chondrocytes, the cellular elements of articular cartilage, have been found to be surprisingly interactive with inflammatory mediators. Most studies supporting this conclusion have been performed *in vitro* on cells cultured from OA or normal cartilage or on immortalized chondrocyte cell lines, but studies involving intact OA cartilage have also demonstrated the production of cytokines by chondrocytes, including IL-1, TNF, and IL-6. It is therefore likely that the chondrocytes in a rheumatoid joint are immunologically active and participate in cytokine networks (see later). Vascular endothelial cells proliferate in rheumatoid synovium and are important contributors to inflammation, as reviewed in Chapter 93.

SOLUBLE FACTORS IN RHEUMATOID SYNOVIUM

Interactions between the various cell types just described are critical for the development and maintenance of synovitis. Cellular communication is mediated by a large number of membrane-bound and secreted factors; the secreted factors have been easier to identify and manipulate and are therefore better understood. Protein mediators secreted by inflammatory cells are categorized as cytokines, chemokines, or growth factors based on the activity that they most prominently display: modulation of immunologic activity, chemotaxis, or cell growth and division, respectively. However, this classification is artificial, and many factors have characteristics of two or all three categories. Detailed knowledge of the function of individual cytokines and other factors in RA has generally come from the study of genetically

manipulated animal models or from studies manipulating the activity of only one or two mediators in explanted synovial tissue or dispersed synovial cells, an environment that may or may not resemble that of unmanipulated tissue.

In this section, rheumatoid synovitis is approached from the viewpoint of the role of soluble mediators in pathogenesis, with particular attention on those that have been investigated both *ex vivo* (in synovial extracts or sections) and *in vitro* (using explants and cell lines) and that have also been assessed in animal models of inflammatory arthritis. The key roles predicted for a few mediators have been convincingly confirmed by using specific inhibitors in patients with RA, thus demonstrating the value of basic scientific investigation in the development of therapies. Table 94.1 provides a summary of cytokines that are relevant to the pathogenesis of RA, their cellular sources, and salient effects.

Tumor necrosis factor

TNF is the prototype of a large family of cytokines. The simplified name TNF is now preferred over the former designation TNF- α because the corresponding term TNF- β , an alternative name for LT, is now obsolete. TNF and other family members are active as trimers, some being secreted and some membrane bound. TNF itself is synthesized first as a membrane-bound protein that is subsequently cleaved to a soluble form, primarily by an enzyme known as TNF- α -converting enzyme (TACE). Both forms of TNF are biologically active. TNF has two cell-surface receptors: TNFR1 (p55) and TNFR2 (p75). Both receptors are ubiquitously expressed,²³ either constitutively (TNFR1) or inducibly (TNFR2). Both receptors can be cleaved from the cell surface to produce soluble proteins that can neutralize TNF and thus play a regulatory role. Soluble p55 and p75 TNFRs are found in both the blood and synovial fluid of RA patients, with concentrations being greater in synovial fluid. TNF production is regulated to a remarkable degree at the posttranscriptional level by a network of positive and negative regulators that act on the 3' end of its mRNA.

TNF is synthesized by a wide variety of cell types, but most prominently by cells of the monocyte-macrophage lineage. These cells appear to be the major producers of TNF in the rheumatoid joint,¹² where this cytokine is readily detected by various methods.^{12,14} TNF production by macrophages *in vitro* is induced by various pathogens and cytokines, including but not limited to IL-1, IFN- γ , and TNF itself. In turn, TNF has a wide range of effects on various cell types and induces the production of numerous cytokines by immune cells, with a net proinflammatory effect. In cultured rheumatoid synovial explants, addition of TNF induces the expression of IL-6, IL-8, and IL-10, and blockade of TNF greatly reduces the production of IL-1 and GM-CSF.⁶¹ Salient effects of TNF on cultured FLSs include induction of prostaglandin E₂, MMPs, and chemokines, including IL-8/CXCL8; TNF and IL-1 often act synergistically in these processes.⁶²

TNF is a critical player in all animal models of inflammatory arthritis in which it has been evaluated, generally by using neutralizing antibodies or soluble receptors or by using mice deficient in TNF.⁶³ The most dramatic demonstration of the ability of TNF to cause arthritis has come from a transgenic mouse aberrantly expressing human TNF as a result of deletion of the aforementioned negative regulatory sequences in its mRNA. This mouse expresses TNF at high levels in synovium, and destructive inflammatory arthritis develops even in the absence of lymphocytes.⁶⁴ IL-1, however, is still essential in this model.

Blockade of TNF with either monoclonal antibodies (infliximab, adalimumab) or a soluble p75 TNFR (etanercept) has proved to be highly effective in treating patients with RA and several other inflammatory diseases. Several features of anti-TNF therapy will be notable as the pathogenesis of RA is considered later in this chapter: prompt improvement in symptoms in the majority of patients, marked improvement in synovial pathology with a significant decrease in the number of activated macrophages, and usually prompt return of disease when anti-TNF therapy is discontinued.

Among the many other members of the TNF superfamily, those that have been implicated in mouse models of RA include LIGHT (TNFSF14) and BlyS/BAFF, and LT is likely to be important in the generation of ectopic germinal centers.

Interleukin-1

Like TNF, IL-1 is the prototype of a phylogenetically ancient family of cytokines that includes IL-1 α , IL-1 β , IL-1Ra, IL-18, and at least six others of little-known function.⁶² IL-1 α is primarily a cytosolic protein and is thought to act in an autocrine manner. It is released from cells only during cell death and therefore circulates in tiny amounts. IL-1 β is also initially cytosolic but is then secreted by a novel and undefined mechanism after cleavage by a

Fig. 94.6 Distribution of interleukin-1 protein in rheumatoid arthritis synovial tissue using an immunoperoxidase technique on a section lacking counterstain. Prominent staining (brown) is seen in the perivascular regions, with less staining in the intimal lining. (Courtesy Dr. M. Field.)

specific protease, the IL-1-converting enzyme (ICE, caspase-1). In addition to this posttranslational regulation, IL-1 production is also regulated transcriptionally and posttranscriptionally.

IL-1 is produced by many cell types relevant in rheumatoid synovitis, including FLSs, endothelial cells, lymphocytes, and neutrophils, but monocytes and macrophages appear to be the major source. IL-1 is readily detected in rheumatoid joints (Fig. 94.6), both in synovial fluid (IL-1 β) and within cells (IL-1 α > IL-1 β).⁶⁵ Synthesis of IL-1 by monocytes *in vitro* is induced by activated T cells and by a variety of cytokines, including TNF and IL-1 itself. Numerous cell types express IL-1RI, and the effects of IL-1 are similar to those of TNF, that is, broadly proinflammatory. Of relevance in the rheumatoid joint, IL-1 stimulates the release of prostaglandin, MMP, and chemokine (IL-8/CXCL8 and others) from FLSs; nitric oxide and prostaglandin production and adhesion molecule expression by endothelial cells; secretion of TNF (and further IL-1) by macrophages; and production of IL-6 and IL-8 but reduced synthesis of proteoglycans by chondrocytes.⁶⁵ In addition, IL-1 and TNF are synergistic in the induction of proteinases, prostaglandins, and cytokines by FLSs. Although IL-1 and TNF upregulate their own and each other's expression, it has been argued that IL-1 is functionally downstream of TNF in the cytokine network of the rheumatoid synovium because blockade of IL-1 does not reduce the synthesis of either TNF or IL-1 in synovial explants,⁶⁶ whereas blockade of TNF markedly reduces the production of IL-1.⁶¹ Blockade of IL-1 in this system does reduce the synthesis of other factors, including IL-6 and IL-8.⁶⁷

The activity of circulating IL-1 (primarily IL-1 β) is regulated by a remarkable array of naturally occurring inhibitors. IL-1Ra, a member of the IL-1 family, is secreted by the conventional endoplasmic reticulum-to-Golgi route; it binds to IL-1RI but does not activate signaling. A second cell-surface receptor for IL-1, IL-1RII, appears to be devoid of signaling potential and thus is viewed as a decoy receptor for excess IL-1. Both IL-1RI and especially IL-1RII also circulate in soluble forms and are thought to perform a similar decoy function.⁶⁵ Finally, antibodies that neutralize IL-1 are induced during immune responses at sufficient levels to have dampening effects.⁶⁷ The overall balance of IL-1 agonists and inhibitors is thought to be the critical factor in whether IL-1 contributes to an inflammatory state. Indeed, although IL-1Ra is detectable in the rheumatoid joint, the ratio of IL-1 to IL-1Ra favors IL-1 and inflammation.¹⁰

Animal models have indicated a central role for IL-1 in inflammatory arthritis. Expression of human IL-1 β in rabbit knee joints causes synovial inflammation,⁶⁸ and local or systemic administration of IL-1 exacerbates arthritis in several mouse models. In mice deficient in IL-1Ra, inflammatory diseases develop that differ depending on genetic background and possibly also environment; inflammatory polyarthritis develops in the BALB/c strain.⁶⁹ Mice deficient in IL-1 or IL-1RI or treated with IL-1Ra or IL-1–blocking antibodies are highly resistant to induction of experimental arthritis in a wide range of models.⁶³ Data from these studies suggest that in mice, IL-1 and TNF both play important roles in inflammation but that IL-1 is more important in joint destruction.

IL-1Ra (anakinra) has been shown to be modestly effective in patients with RA and interferes with both inflammation and joint destruction. Based on studies in animal models, it might have been predicted that IL-1 blockade

Fig. 94.7 Dark-field view of *in situ* hybridization identifying interleukin-6 messenger RNA expression in rheumatoid arthritis synovium.

would be as effective as TNF blockade in controlling inflammation, which has not been borne out in humans. This discrepancy may reflect either the unfavorable pharmacokinetics and pharmacodynamics of current methods of IL-1 blockade or fundamental differences in pathogenic mechanisms between animal models and human RA.

T cell–derived cytokines: IL-2, IL-4, IL-5, IL-13, and IFN- γ

Space constraints do not permit full discussion of the cytokines primarily produced by T cells, but one of the most striking findings in the study of mechanisms of chronic synovitis is the lack of evidence of the importance of these cytokines to the pathogenesis of RA.

Interleukin-6

IL-6 is the prototype of a family of cytokines that share a common signal transduction pathway. Its receptor consists of two chains: a ligand-specific IL-6R that is found on most hematopoietic and some nonhematopoietic cells and a signal-transducing chain, gp130, that is found on most cell types and is used by all the IL-6 superfamily members. A soluble form of IL-6R (sIL-6R) exists and serves to promote signaling when bound by IL-6 rather than functioning as a blocking or decoy receptor as do the soluble receptors for TNF and IL-1. IL-6 has many effects on hematopoietic and nonhematopoietic cells, both proinflammatory and antiinflammatory. It is perhaps best known for stimulating B cells to increase IgG production and differentiate into plasma cells. IL-6 is an endogenous pyrogen and a potent inducer of the acute-phase response in the liver.

In RA, IL-6 is produced by FLSs²⁴ and by chondrocytes,¹¹ but the major local source is probably macrophages (Fig. 94.7).^{11,70} Production is induced synergistically by TNF and IL-1. In turn, however, IL-6 decreases expression of TNF and IL-1, as well as the neutrophil-attracting chemokines CXCL8/IL-8 and CXCL1/MIP-2.⁷¹ Levels of IL-6 are elevated in the synovial fluid and serum of patients with RA, and serum levels correlate with levels of acute-phase reactants.⁷²

Blockade of IL-6 activity reduces or prevents arthritis in several mouse models, but only in those that include a phase of induction of autoimmunity after immunization. IL-6 has not been found to have a role in the effector phase of experimental arthritis after the production of autoantibodies.⁶³ A blocking antibody against human IL-6R (tocilizumab) has been shown to be effective in improving both symptoms and inflammatory markers (especially C-reactive protein) in RA in several controlled clinical trials.⁷³

Other cytokines of the IL-6 family that are being studied for potential roles in RA include oncostatin M (OSM), IL-11, and leukemia inhibitory factor (LIF).

Interleukin-10

More clearly than the IL-4 family members, IL-10 is a predominantly anti-inflammatory cytokine. Though initially described as a characteristic product of the Th2 subtype of CD4+ T cells, IL-10 is made in larger amounts

by macrophages and is also produced by Tregs and other cell types. Non-T cells, presumably macrophages, appear to be the major producers of IL-10 in rheumatoid synovium.⁷⁴ IL-10 levels are higher in RA than in OA synovial fluid,⁷⁴ and increased IL-10 levels are inversely correlated with joint destruction.⁷⁵ In cultures of synovial fluid mononuclear cells, blockade of IL-10 increases and the addition of IL-10 decreases the production of IL-1, TNF, and other inflammatory mediators.⁷⁶ The actions of IL-10 are not universally immunosuppressive, however, because this cytokine can stimulate B cells to proliferate and differentiate into plasma cells *in vitro*.

IL-10 has been studied extensively in animal models. An inflammatory bowel disease that is dependent on TNF and IL-1 develops spontaneously in IL-10-deficient mice. Collagen-induced arthritis is more severe in IL-10-deficient mice, but the arthritis induced by anticollagen antibodies is, surprisingly, less severe.⁷⁷ Addition of IL-10 by gene transfer in the active immunization model of collagen-induced arthritis decreases inflammation, but only if therapy is begun before clinical evidence of disease.⁷⁸ IL-10 gene therapy also decreases invasion of pannus into cartilage in a model in which human cartilage and synovium are cotransplanted into SCID mice.⁷⁹ Efforts to use recombinant IL-10 to treat established human RA have been disappointing.

IL-19, IL-20, and IL-22 are homologues of IL-10 but have proinflammatory activity. All these cytokines are expressed in RA synovium, but their roles in RA or in animal models are not yet known.

Interleukin-12 and interleukin-23

IL-12 is primarily of macrophage origin and is a major driver of Th1 differentiation and secretion of IFN- γ by both T cells and NK cells. IL-12 is a heterodimer composed of two subunits, p40 and p35. The p40 subunit is also used by IL-23, and indeed, mice lacking p40 or treated with antibodies that block p40 are deficient in IL-23, as well as in IL-12. IL-23 is a major driver of Th17 differentiation.

IL-12 and IL-23 are expressed in rheumatoid synovium, but whether at levels greater than those found in OA is unclear.⁸⁰ Divergent results have been reported with manipulation of IL-12 in the mouse model of collagen-induced arthritis, but before the distinction between IL-12 and IL-23 was recognized. A recent study comparing mice lacking either IL-12 or IL-23, but not both, has helped clarify this issue. IL-23-deficient mice were completely resistant to collagen-induced arthritis, whereas more severe disease developed in IL-12-deficient mice,⁸¹ thus suggesting that IL-23 is an essential mediator of arthritis whereas IL-12 protects against it.

Interleukin-15

IL-15 invites comparison with IL-2 by virtue of their shared signaling apparatus, but IL-15 and its receptor are much more widely expressed.⁸² Based on the phenotype of IL-15-deficient mice, the salient function of IL-15 is as a survival factor for naive T cells, particularly CD8+ cells, but this cytokine has other, generally proinflammatory effects as well.

In rheumatoid synovium, IL-15 is prominently expressed by lining macrophages but is also found in FLSs and endothelial cells,¹⁵ and it is secreted in sufficient amount to be detectable in synovial fluid in RA but not OA. Studies of patients with RA have demonstrated a significant relationship between levels of IL-15 and TNF in synovial fluid (Fig. 94.8). *In vitro*, IL-15 is important in the contact-dependent stimulation by T cells of TNF production from macrophages⁸³ and in the stimulation of T cells by FLSs. In mice, recombinant IL-15 can replace adjuvant in the induction of collagen-induced arthritis, thereby obviating the need for the immunostimulatory mycobacterial products present in complete Freund adjuvant. Conversely, blockade of IL-15 or IL-15R decreases the severity of collagen-induced arthritis.⁸⁴

Interleukin-17

IL-17 has proinflammatory effects on a variety of cell types, which leads to the induction of prostaglandins, nitric oxide, cytokines, and chemokines. Six IL-17 family members have been identified (IL-17A to IL-17F), and IL-17A is a proinflammatory cytokine whose importance in the pathogenesis of RA has already been highlighted. IL-17A and IL-17F are produced by Th17 cells. IL-17 induces IL-1 and TNF production in synovial macrophages and fibroblasts^{85,86} and can be synergistic with IL-1 in the upregulation of certain inflammatory mediators produced by FLSs. Some unusual activities ascribed to IL-17 include induction of osteoclastogenesis through upregulation of RANKL (receptor activator of nuclear factor κ B [NF- κ B] ligand) on osteoblasts and synovial fibroblasts⁸⁷ and stimulation of the synthesis of complement components by fibroblasts.

Fig. 94.9 Immunohistochemistry demonstrating interleukin-18 (IL-18) staining in rheumatoid arthritis synovium. (a) IL-18-expressing cells (brown) in lymphoid aggregate. (b) Neutralization of staining with recombinant IL-18. (c) IL-18 expression in cultured synovial fibroblasts. (Courtesy Drs. J.A. Gracie and I.B. McInnes.)

Synovial explants from the great majority of RA patients, but from few OA and nonarthritic patients, secrete IL-17.⁸⁸ Expression is high in T cell-rich areas, as expected.⁸⁸ In these explants, production of IL-17 is inhibited by the addition of two of the cytokine products of Th2 cells, IL-4 or IL-13, and IL-17 appears to be important for the local production of IL-6.⁸⁸ IL-17R uniquely binds IL-17 and is expressed on various synovial cell types in different arthritides, most notably endothelial cells and chondrocytes.

Blockade of IL-17 reduces inflammation, joint damage, and systemic levels of IL-6 in the mouse model of collagen-induced arthritis. This therapeutic effect occurs even if treatment is started after the onset of clinical disease, thus indicating that the proinflammatory rather than solely the immunomodulatory effects of IL-17 are important in this model.⁸⁹

Interleukin-18

IL-18 is related in structure to IL-1 and also has broadly proinflammatory actions. In rheumatoid joints, macrophages,⁹⁰ FLSs,⁹¹ and chondrocytes can all produce IL-18, although there is some disagreement regarding whether macrophages are the predominant cell type producing this cytokine (Fig. 94.9).^{90,91}

IL-18R is a heterodimer of α and β chains, and its intracellular signaling is similar or identical to that of IL-1R. Soluble splice variants of the IL-18R

α chain are secreted, can block the activity of the cytokine, and thus may play a role in regulation.⁹¹ IL-18R is expressed on many cell types potentially relevant to synovitis, including naive T cells, NK cells, macrophages, neutrophils, and chondrocytes. Notably, however, the β chain is not expressed on rheumatoid FLSS.⁹² Based on experiments in mice and *in vitro*, IL-18 promotes Th1 responses and IFN- γ secretion (particularly in combination with IL-12), RANKL expression, and osteoclastogenesis through actions on T cells and macrophage production of TNF and the innate immune receptors TLR2 and TLR4.

IL-18 mRNA and protein are found at higher levels in RA than in OA synovium,¹⁷ and IL-18 levels correlate with other markers of disease activity.⁹³ In synovial explants, addition of TNF and IL-1 induces the production of IL-18, and addition of IL-18 induces TNF, IFN- γ , GM-CSF, and nitric oxide.¹⁷ Thus, IL-18, like IL-1, probably plays an important role in the cytokine network in rheumatoid synovitis. In mice, IL-18 can promote collagen-induced arthritis by substituting for adjuvant.¹⁷ IL-18-deficient mice have a decreased incidence of collagen-induced arthritis, with defects in both the priming and effector phases of disease,⁹⁴ and anti-IL-18 antibodies inhibit the arthritis induced by injection of streptococcal cell wall material.⁹⁵ In addition, IL-18 is a chemoattractant for T cells, derived from RA synovium, that express IL-18R.

Transforming growth factor- β

TGF- β is the prototype of a large family of mediators that includes the bone morphogenic proteins (BMPs). It is broadly immunosuppressive and anti-inflammatory, but as an example of its complex actions, it can both stimulate and inhibit angiogenesis under different conditions. TGF- β increases the production and decreases the breakdown of extracellular matrix (ECM) and is thought to be a major factor in both physiologic wound healing and pathologic fibrosis.

TGF- β activity is readily detectable in rheumatoid synovial fluid,⁹⁶ and by immunohistochemistry TGF- β_1 is present at increased levels in RA versus OA synovial tissue,⁹⁷ apparently produced by macrophages, FLSS, endothelial cells,⁹⁷ chondrocytes,¹¹ and DCs⁹⁸; TGF- β_2 and TGF- β_3 appear to be synthesized at lower levels.⁹⁸ TGF- β has many effects when added to FLSS *in vitro*, including an increase in the synthesis of fibronectin-rich matrix, a decrease in the secretion of hyaluronic acid, and inhibition of induced apoptotic cell death.

The suppressive effects of TGF- β on experimental arthritis have been shown by using purified cytokine or blocking antibodies. Mice engineered so that TGF- β signaling is defective only in T cells are more susceptible to collagen-induced arthritis.⁹⁹ Conversely, local injection of TGF- β into affected knee joints in murine arthritis induced by zymosan (a direct activator of complement) does not decrease inflammation but does restore the proteoglycan content of cartilage.¹⁰⁰ In addition, some investigators have found a genetic association between a polymorphism in the TGF- β_1 gene and the incidence or severity of human RA.

Other cytokines and growth factors

Space limitations prevent discussion of these mediators in detail, but it is worth noting that the distinction between cytokines and growth factors is somewhat arbitrary. Just as cytokines influence the growth and function of nonimmune cells in the RA joint, so do these growth factors also influence immune cells and the network of inflammatory mediators. Macrophage migration inhibitory factor (MIF), OSM, and three hematopoietic colony-stimulating factors (GM-CSF, G-CSF, and M-CSF) have all been implicated in promoting inflammatory arthritis in mouse models.

Chemokines

Chemokines, the name being an abbreviation of the term *chemotactic cytokines*, are protein mediators that cause the migration of various cell types, usually toward the source or highest concentration of the stimulus. Forty-eight human chemokines and 19 chemokine receptors have been described, with multiple ligands binding to a given receptor and, for additional complexity, multiple receptors often binding a given ligand. Both are grouped into four families—CC, CXC, C, and CX₃C—based on the positions of conserved cysteine residues.

The biology of chemokines is so complex that it makes detailed discussion here impractical. The potential roles for specific chemokines in RA have been reviewed in detail.¹⁰¹ Although chemokines as a group are clearly critical for the production of inflammation, the prospect of treating RA by blocking one or two chemokines is made challenging by the striking redundancy of the system.

Arachidonic acid metabolites

Prostaglandins and leukotrienes are lipid mediators that are generally pro-inflammatory. The cyclooxygenase enzymes (COX-1 and COX-2) and the leukotriene-producing enzymes are expressed by multiple cell types in rheumatoid synovium, and prostaglandin E₂ (PGE₂) and leukotriene B₄ (LTB₄) are important in multiple animal models. However, it is notable that although nonsteroidal antiinflammatory drugs have a long track record in treating the symptoms of RA, they do not appear to be disease modifying, and reports of the use of leukotriene inhibitors and antagonists for RA have been few and preliminary. Probable roles for more recently described anti-inflammatory lipids such as lipoxins are also being investigated.

Ligands for Toll-like receptors

TLRs are a family of membrane-associated receptors that are activated by a variety of unique microbial products and play an important role in “innate” immunity, that is, antimicrobial defense that does not require the development of antigen-specific T- or B-cell responses. Activation of TLRs stimulates proinflammatory pathways in leukocytes, endothelial cells, and parenchymal cells and also promotes antigen-specific immune responses both directly in B cells and indirectly via antigen presentation to and co-stimulation of T cells.¹⁰² In addition to microbial products, endogenous molecules (e.g., hyaluronic acid, HMGB1, heat shock proteins, chromatin, and fibrinogen) have also been shown to interact with and activate TLRs *in vitro*. Because these endogenous molecules are released in association with cell death and tissue damage, settings in which host defense needs to be activated, their binding to TLRs is probably relevant *in vivo* as well and particularly in chronic inflammatory diseases.¹⁰²

All these putative endogenous TLR ligands are abundant in joints with established RA. In addition, bacterial products have been detected in a majority of joints inflamed as a result of different causes.¹⁰³ TLRs are expressed on multiple cell types in RA synovium. For example, TLR1 through TLR6 but not TLR7 to TLR10 are expressed by FLSS,¹⁰⁴ and expression of TLR2, TLR3, and TLR4 is higher in RA than in control fibroblasts.^{104,105} Stimulation of TLR2 induces the secretion of several chemokines, VEGF, MMPs, and IL-15 by FLSS.¹⁰⁶⁻¹⁰⁹ Expression of TLR2 and TLR4 is also elevated on macrophages in inflamed synovium,^{110,111} and ligation of these receptors leads to the production of TNF and IL-8.¹¹¹

TLRs play complex roles in mouse models of RA as well. Certain TLR ligands can produce inflammatory arthritis after intraarticular injection: hypomethylated CpG-containing DNA via TLR9¹¹² and streptococcal cell walls via TLR2.¹¹³ Stimulation of TLR4 by bacterial LPS facilitates the induction of arthritis by antibodies to type II collagen or glucose-6-phosphate isomerase (GPI),^{38,114} and blockade or absence of TLR4 reduces the severity of collagen-induced arthritis, chronic streptococcal cell wall-induced arthritis, and spontaneous arthritis arising in mice genetically lacking IL-1Ra.¹¹⁵⁻¹¹⁷ On the other hand, stimulation of TLR9 or TLR3 ameliorates different autoantibody-mediated arthritides via induction of type I interferons,^{38,118} and absence of TLR2 is associated with more severe arthritis in mice lacking IL-1Ra.¹¹⁷ Interference with signaling via the endosomally localized TLR3, TLR7, and TLR9 has been proposed as an important mechanism of action of antimalarial agents in treating autoimmune inflammatory diseases.¹¹⁹

Complement and immune complexes

Circulating complement is depleted in RA only in the setting of rheumatoid vasculitis. However, RA is apparently unique among the arthritides in the depletion of complement in synovial fluid in comparison to blood.¹²⁰ In addition, complement degradation products are found in rheumatoid synovial fluid. Deposits containing both immunoglobulin and C3 are readily detected in the articular cartilage of patients with RA (Fig. 94.10). Similar deposits are found in articular cartilage in various mouse models; in the K/BxN mouse model, for example, these deposits also contain the specific target antigen GPI.¹²¹ Arthritis in several mouse models is dependent on the complement cascade and particularly on C5. Together, these findings suggest that immune complexes form or are deposited in RA joints and locally activate complement, with the probable consequence of chemotaxis and activation of leukocytes by the cleavage products C3a and C5a. Which autoantibodies participate in the formation of these immune complexes is unknown; antibodies of several specificities, including RF, ACPA, and anti-type II collagen, are found at higher concentration in synovial tissue than in the circulation, but whether this finding indicates local deposition in addition to local synthesis is unclear.

Arthritis in several mouse models is also dependent on the low-affinity stimulatory receptor for IgG, Fc γ RIII. The low-affinity inhibitory FcR,

Fig. 94.10 Deposition of IgG (a, red) and C3 (b, green) on the cartilage surface of the knee, as shown by immunofluorescence staining. The patient was an 82-year-old woman with a 10-year history of rheumatoid factor–positive rheumatoid arthritis.

FcγRII, plays a protective role against arthritis in these models. Because low-affinity FcRs bind to aggregated but not monomeric IgG, their importance provides evidence for a key role in the handling of either immune complexes or surface-bound IgG in these models. Although roles for the FcRs have not been directly investigated in RA, polymorphisms in the genes for FcγRIIIA and FcγRIIA (both stimulatory, low-affinity FcRs) have been linked to susceptibility to or severity of RA by several groups.

JOINT DESTRUCTION

Enzymatic destruction of components of the ECM is the major mechanism proposed for the cartilage, ligament, and tendon destruction in RA. In particular, cartilage destruction has been attributed to the combined actions of several distinct families of proteinases, each of which has defined substrate specificity. Proteinases are produced by cells within the invasive pannus tissue, by cells in the synovium remote from bone, and by chondrocytes themselves under certain conditions of activation. These enzymes represent a potential therapeutic target for protection from joint destruction in RA.

Matrix metalloproteinases

Perhaps the best studied family of enzymes implicated in the joint destruction in RA is the MMP family, whose member interstitial collagenase (MMP-1) was the first to be identified in media from cultured RA synovial tissue.¹²² Subsequently, studies using *in situ* hybridization of whole synovial tissue identified synoviocytes within the synovial lining layer as the exclusive source of mRNA for MMP-1 and another MMP family member, stromelysin-1 (MMP-3), in RA synovium (Fig. 94.11).¹²³ In addition, MMP-1 and MMP-3 proteins have been demonstrated in synovium remote from bone, as well as at sites of cartilage erosion.¹²⁴ Several additional MMP family members have now been identified as being expressed in RA synovial tissue or in synovially derived pannus tissue invading into cartilage. MMPs can act at neutral pH and have the ability, in aggregate, to degrade the components of the ECM of cartilage.

The MMP family comprises 25 members. Classification of an enzyme as a member of this family depends on the presence of conserved “pro” and “catalytic” domains. These enzymes are named “metallo” because of the presence of a zinc ion in the active site of the catalytic domain. Within the prodomain is a conserved cysteine residue that interacts with Zn²⁺ in the catalytic domain. When this interaction is disrupted by removal of the propeptide via proteolytic cleavage, the enzyme’s active site becomes available and the enzyme is thus activated. Expression of MMP enzymes is regulated at several steps, including at the levels of gene transcription, activation of the proenzyme to the active enzyme, focality of expression within tissues, and finally, enzyme inactivation.¹²⁵

Collagenases

Collagenases were the first of the MMP enzymes to be implicated in the process of cartilage destruction in RA. This group of enzymes cleaves the collagen triple helix at a defined site near its N-terminus. Accordingly, the major substrates of the collagenases are native interstitial collagens types I and II, the latter being the predominant collagen component of cartilage.¹²⁵ Members of this group include fibroblast or interstitial collagenase (collagenase-1, MMP-1), neutrophil collagenase (collagenase-2, MMP-8), and collagenase-3 (MMP-13).

Neutrophil collagenase (MMP-8) and collagenase-3 (MMP-13) have also been implicated in the joint destruction in RA. In particular, MMP-13 is

Fig. 94.11 Bright-field image of *in situ* hybridization in rheumatoid arthritis synovial tissue. A low-power view demonstrates abundant expression of mRNA (black dots) for matrix metalloproteinase-3 (stromelysin-1). (From Gravalles EM, Darling JM, Ladd AL, et al. *In situ* hybridization studies of stromelysin and collagenase messenger RNA expression in rheumatoid synovium. *Arthritis Rheum* 1991;34:1076-84. Reprinted with permission of Wiley-Liss, Inc., Wiley Publishing, Inc., a subsidiary of John Wiley & Sons, Inc.)

expressed by cells within the RA synovium, as well as by chondrocytes in areas of cartilage damage. Because MMP-13 is efficient in cleaving native collagens, as well as aggrecan, and because gene expression of MMP-13 is also upregulated by TNF and IL-1, this enzyme has been implicated as a uniquely important therapeutic target for protection against cartilage destruction in RA.

Stromelysins

The stromelysin group of MMPs has broad substrate specificity for components of the ECM. This group of enzymes degrades noncollagen connective tissue components, including proteoglycans, fibronectin, and laminin, as well as some of the minor collagens. In addition, MMP-3 has the ability to cleave and activate procollagenase, thereby providing additional matrix-degrading capability. The first observation of the potential importance of MMP-3 in inflammatory arthritis was the demonstration, in Lewis rats with streptococcal cell wall–induced arthritis, of transin (MMP-3 rat homologue) protein in the synovial lining layer and in the underlying stroma.¹²⁶ However, when collagen-induced arthritis was generated in MMP-3–deficient mice, severe inflammation and cartilage and bone destruction resulted, thus demonstrating that MMP-3 is not unique in its matrix-degrading capability.¹²⁷

Of the three members of the stromelysin group (stromelysin-1 [MMP-3], stromelysin-2 [MMP-10], and stromelysin-3 [MMP-11]), MMP-3 is by far the most abundantly expressed in RA. *In situ* hybridization studies demonstrate that like MMP-1, gene expression of MMP-3 is greater in RA than in OA synovium.¹²³ Although very low levels of MMP-3 are expressed by unstimulated synoviocytes, TNF and IL-1 are potent stimulators of MMP-3 gene expression, as are fibronectin fragments through engagement and cross-linking of fibronectin receptors on synoviocytes.

Other matrix metalloproteinases and related enzymes

Other MMP family members have been implicated in the process of cartilage destruction in RA, including the gelatinases: gelatinase A (72-kDa gelatinase, MMP-2) and gelatinase B (92-kDa gelatinase, MMP-9). These enzymes are expressed in RA synovium and can degrade partially cleaved collagens (gelatins). Aggrecan is a major proteoglycan component of articular cartilage. Cleavage of the aggrecan core protein in cartilage leads to destabilization of the protein with subsequent loss of cartilage compressibility. Although several MMPs can cleave aggrecan, it has long been clear that another enzyme or enzymes must also be responsible for cleavage because products were found in which cleavage took place between Glu373 and Ala374, a site that none of the known MMPs is able to cleave. A related but distinct family of enzymes was thus identified that may also play a role in the cartilage destruction in RA—the ADAMTS (a disintegrin and metalloproteinase with thrombospondin motifs) family of proteinases. Two members of this family implicated in cartilage destruction are aggrecanase-1 and aggrecanase-2, both of which are expressed in synoviocytes and synovial tissue in RA and OA.

Role of matrix metalloproteinases in inflammation

Although MMPs have long been considered to be enzymes whose purpose is to remodel and degrade the components of the ECM, data have

demonstrated that these enzymes also play an important role in regulating the process of inflammation. It has become clear that many MMPs can also act on nonmatrix proteins, including cytokines, chemokines, and their receptors, and play a role in the innate immune system and in tissue repair.¹²⁵ The role of MMPs in the inflammatory process is evident from the results of experiments in which mice deficient in certain MMPs were challenged with inducers of arthritis. Surprisingly, a more severe immune-mediated arthritis developed in MMP-2-deficient and MMP-3-deficient mice than in their control littermates,^{127,128} thus suggesting that these enzymes may actually provide protection from inflammation, whereas less severe arthritis developed in MMP-9-deficient mice.¹²⁸

Protease inhibitors

In addition to the regulatory mechanisms described earlier, the activity of MMP enzymes is also regulated by naturally occurring inhibitors, including the tissue inhibitors of metalloproteinases (TIMPs), of which four family members are recognized (TIMP-1 to TIMP-4). Specific TIMPs have affinity for specific MMP family members and act by binding with high affinity to the catalytic domain of the enzyme in a 1:1 stoichiometry to render it inactive. Two other known inhibitors of MMP activity are α_2 -macroglobulin, which binds active MMP enzyme in the circulation, and RECK (reversion including cysteine-rich protein with kazal motifs), which inhibits the function of MMP-2, MMP-9, and MMP-14. The α_2 -macroglobulin molecule forms a covalent link with the protease to render it inactive and is the main inhibitor of collagenase activity in serum. Neutrophil-derived elastases and serine proteinases can in turn inactivate α_2 -macroglobulin.

Cysteine and serine proteases

Since discovery of the MMP family of enzymes in RA synovium and pannus, several other classes of enzymes have also been reported to be expressed by cells within RA synovial tissue or pannus tissue (or both) and have been implicated in causing cartilage destruction in arthritis. Included among these are the cysteine protease family of enzymes, especially cathepsins B, L, and K. As a class, the cathepsins have a wide range of substrate specificity, including native collagens, proteoglycans, fibronectin, fibrinogen, elastin, and laminin. Cathepsin K is another family member implicated in joint destruction. This enzyme is secreted in high amount by osteoclasts and is largely responsible for the degradation of type I collagen in bone by these cells. Cathepsin K is also expressed by synovial fibroblasts in RA. The serine proteinases, including granzymes, neutrophil elastase, and mast cell chymases, have also been implicated in the joint destruction in RA. In addition, several of these enzymes have the ability to activate pro-MMPs. Serine proteinase inhibitors (SERPINs) are present in plasma and synovial fluid and serve to block ECM degradation by this class of enzymes.

Bone destruction

Although the action of proteinases in degrading the various components of the ECM probably plays a major role in the destruction of cartilage, tendon, and ligament in RA, destruction of bone requires removal of the mineralized bone matrix. In physiologic bone remodeling associated, for example, with microfracture or altered mechanical loading, removal of bone is accomplished by osteoclasts. Osteoclasts are specialized cells, differentiated from cells of the monocyte-macrophage lineage, that have the capacity to bind to the surface of bone and create a tight "attachment zone" via interactions between integrins, including $\alpha_v\beta_3$, on the osteoclast membrane and matrix components in bone, including bone sialoprotein and osteopontin. Creation of this tight seal with bone allows the osteoclast to generate an acidic environment through the action of carbonic anhydrase II and a proton pump, thereby leading to removal of mineral from bone. Osteoclasts also release lysosomal proteinases into this acidic environment, perhaps the most important of which is cathepsin K, as well as enzymes of the MMP group, including MMP-9, which leads to degradation of the organic component of the bone matrix.

A role of osteoclasts in the focal bone erosion in RA was suspected initially on the basis of indirect evidence, including identification of multinucleated cells at sites of erosion in subchondral bone and at the pannus-bone interface in tissue samples from patients with RA (Fig. 94.12).¹²⁹ Studies using immunohistochemistry and *in situ* hybridization have demonstrated that these multinucleated cells express characteristic markers of osteoclasts, including a marker unique to osteoclasts.¹³⁰ Similarly, osteoclasts have been identified at erosive surfaces in arthritic joints in numerous animal models of RA.

Fig. 94.12 Focal subchondral bone erosion in rheumatoid arthritis. Note that osteoclasts are present at a site of resorption. (From Gravalles EM, Goldring SR. Cellular mechanisms and the role of cytokines in bone erosion in rheumatoid arthritis. *Arthritis Rheum* 2000;43:2143-51. Reprinted with permission of Wiley-Liss, Inc., Wiley Publishing Inc., a subsidiary of John Wiley & Sons Inc.)

Our understanding of the pathogenesis of bone erosion and the role of osteoclasts in RA was greatly augmented by the discovery of a cytokine system now known to be the key regulatory system of osteoclast differentiation and activation. RANKL, also known as osteoprotegerin ligand (OPGL), osteoclast differentiation factor (ODF), and TNF-related activation-induced cytokine (TRANCE), is a cytokine initially identified as being important in the regulation of interactions between DCs and T lymphocytes, as well as in regulating lymph node organogenesis and lymphocyte development.^{131,132} It was also recognized that RANKL is essential for osteoclast differentiation and activation, thereby providing a link between the immune system and bone. RANKL binds to its receptor RANK, present on osteoclast precursor cells, to effect its biologic functions. OPG, a decoy receptor for RANKL, is the third member of this cytokine system. OPG can bind to RANKL with high affinity, thus preventing binding of RANKL to RANK and blocking the biologic activity of RANKL (Fig. 94.13). The expression of RANKL protein relative to OPG protein at a given site is the critical determinant of the degree to which osteoclast-mediated bone resorption occurs at that site.

RANKL is expressed predominantly by two cell types within rheumatoid synovial tissue: FLSs and T cells.¹³³ Cells isolated from cultured RA synovium also generate multinucleated cells that can resorb bone,¹³⁴ a definitive demonstration that these multinucleated cells are osteoclasts. RANKL is expressed at sites of bone resorption in tissue from patients with RA (Fig. 94.14). The first definitive demonstration of the critical role of RANKL and osteoclasts in the bone erosion in arthritis was reported in studies using the rat adjuvant-induced arthritis model, a model in which activated T cells have been shown to express RANKL protein. Treatment of arthritic rats with OPG was initiated at disease onset, and it was demonstrated that although levels of inflammation were similar in treated and untreated rats, arthritic rats treated with OPG exhibited complete protection from bone erosion.¹³⁵ Furthermore, studies in mice deficient in osteoclasts (as a result of deficiencies in different factors critical to osteoclastogenesis), including RANKL-deficient mice¹³⁶ and c-fos-deficient mice,¹³⁷ have demonstrated dramatic protection from bone erosion in models of experimental arthritis driven by autoantibodies or by overexpression of TNF, respectively.

In addition to the RANKL/RANK/OPG system, other cytokines and growth factors produced by synovial tissue or pannus tissue in RA can influence the differentiation and activation of osteoclasts. Factors that can play a direct role in osteoclast differentiation include TNF, which is a potent differentiation factor for osteoclast precursor cells in synergy with RANKL; M-CSF, which expands the pool of osteoclast precursor cells; and IL-1, which prevents apoptosis of osteoclasts and augments their bone-resorbing potential.^{138,139} Therapeutic blockade of IL-1 or TNF in patients with RA can modulate both inflammation and bone erosion.^{140,141} In addition, factors produced by RA synovial tissue, including IL-1, TNF, and parathyroid hormone-related protein, may act indirectly on osteoclast genesis and activity by increasing the RANKL/OPG expression ratio in the local bone micro-environment. T cells within the rheumatoid lesion may also contribute to osteoclast-mediated bone resorption, not only via expression of RANKL by activated T cells but also via production by a subset of T cells of IL-17, which is a potent stimulator of osteoclastogenesis by indirect mechanisms. The rheumatoid synovium is also a source of factors that can inhibit osteoclastogenesis, including IL-4, IL-10, IFN- β , and IFN- γ .

Fig. 94.13 Osteoclasts are derived from cells of the monocyte-macrophage lineage. Macrophage colony-stimulating factor (M-CSF) derived from bone-lining (stromal) cells induces expansion of the osteoclast precursor pool and expression of receptor activator of nuclear factor κ B (RANK). Binding of the RANK ligand (RANKL) to RANK leads to osteoclast differentiation, fusion, and activation. Tumor necrosis factor (TNF) can synergize with RANKL to induce osteoclast differentiation. Possible sources of RANKL in rheumatoid arthritis (RA) include bone-lining cells, fibroblast-like synoviocytes (FLSs), and activated T cells. Bone stromal cells and FLSs are also sources of the RANKL decoy receptor osteoprotegerin (OPG). Cells from RA synovium produce factors that could influence osteoclast differentiation, fusion, and activation at a number of steps. In addition, activated macrophages from synovial tissue can act as osteoclast precursor cells. IL-17, interleukin-17.

PATHOGENESIS

Any theory of the pathogenesis of RA must extend beyond observations of synovial pathology and consider the epidemiology and clinical features of the disease as well. Although patients with RA often have extraarticular features, the dominant and defining clinical manifestation of this disease is chronic inflammation of joints lined by synovium. This fact undoubtedly provides a significant clue to the pathogenic mechanisms underlying RA. One can propose a host of factors that could contribute to the joint-specific

nature of RA, including unique structural features of the joint and the proximity of synovium to cartilage and bone, unique cell populations within the joint and the organization of these cell types, tropism of pathogens to the joint, and joint-specific antigens (Box 94.1). Contributions from these factors are not mutually exclusive, and it is likely that some—or many—may play a role in the initiation or chronicity of this disease, or in both.

Genetics and autoimmunity

Twin studies have indicated both that genetic and nongenetic (environmental or “chance”) factors are involved in RA. A major breakthrough in our understanding of the pathogenesis of RA came from studies demonstrating a genetic link to HLA-DR genes containing a common five-amino acid motif known as the “shared epitope”¹⁴²; subsequent genome-wide association studies have identified polymorphisms in multiple additional genes plausibly related to lymphocyte activation or inflammation (see Chapter 89). Because HLA-DR proteins present peptide antigens to CD4+ T cells, the existence of a shared epitope strongly suggests a role for T cells in the pathogenesis of RA and implies that one or a few antigenic peptides initiate or “drive” disease in patients expressing the shared epitope. Citrullinated peptides from fibrinogen bind to a shared-epitope HLA molecule,¹⁴³ and shared-epitope HLA genes are associated with ACPA-positive but not ACPA-negative RA. Nevertheless, it is premature to conclude that presentation of citrullinated peptides to T cells by shared-epitope HLA molecules is “the cause” of RA. It is sobering to note that no single peptide antigen has been identified to underlie the much stronger association of HLA-B27 with ankylosing spondylitis.

One additional clinical feature of RA that must be taken into account in any discussion of the pathogenic mechanisms of disease is the presence of circulating autoantibodies, not only ACPA but also RF and others that are not in clinical use. Strikingly, detectable serum RF and ACPA usually

precede the clinical onset of RA, often by many years.¹⁴⁴ The best interpretation of these data is that humoral autoimmunity, following a breakdown in T-cell tolerance, precedes chronic inflammation in RA, thus suggesting that autoantibodies and possibly immune complexes play a role in disease pathogenesis. To gain further insight into the pathogenic mechanisms involved in RA, investigators have turned to animal models in an attempt to define both the events that may initiate the disease and those that can produce a state of chronic synovitis that eventually leads to the destruction of joint structures.

Lessons from animal models

All animal models of RA differ in important ways from the human disease, most notably in their rapidity of onset and progression, the details of the autoimmunity, and the requirement for either immunization or an overt genetic defect or manipulation (see Chapter 90). Starting from the perspective that models help define what could cause a human disease rather than what does or does not, the first important lesson from study of the large and growing number of animal models of RA is that there are many ways to cause a pathologic process that resembles the human disease. Second, these studies clearly demonstrate that TNF and IL-1 are critical players in all the models in which they have been evaluated⁶³ and that dysregulated overexpression of these cytokines in the joint is sufficient to cause chronic arthritis.^{64,68}

Thus, any mechanism leading to excess TNF and IL-1 in the joint would probably produce RA-like disease. This can readily be achieved by adaptive immunity to autoantigens or foreign antigens, beginning with the activation of T cells and leading in many models to the production of pathogenic autoantibodies. Activation of innate immune cells, including macrophages, mast cells, and neutrophils, may prime the joint for subsequent inflammation. Moreover, it is essential that cells of the innate immune system, to different degrees in different models, be recruited to the joint to mediate the proinflammatory effects of immune complexes or T cells (or both). However, the adaptive immune response is critical for the production of TNF and IL-1 and the subsequent development of arthritis in most models.⁶³ How, then, is the chronic production of TNF and IL-1 achieved in human RA and what are the roles of T cells, B cells, autoantibodies, and immune complexes in the pathogenesis of this disease?

In what way is the pathogenesis of rheumatoid arthritis dependent on T cells?

The strong association of ACPA-positive but not ACPA-negative RA with HLA alleles containing the shared epitope strongly implicates CD4+ T cells reacting to citrullinated antigens in pathogenesis. However, it may be that the role of antigen-specific T cells is primarily or entirely to provide help for B cells in producing ACPA. Most T cell-derived cytokines are not prominent in synovium, and T cells isolated from synovium behave more like T cells stimulated by cytokines than like T cells stimulated by antigen. Further evidence against a prominent role of CD4+ T cells in established RA might seem to be obtained from disappointing clinical trials of anti-CD4 antibodies, but follow-up studies have indicated that this agent did not cause depletion within the synovium as expected. The clinical effectiveness of abatacept (CTLA4-Ig) in human RA argues that co-stimulation of T cells remains important throughout the natural history of RA, but it is difficult to rule out effects of this drug on the antigen-presenting cells (including macrophages, B cells, and DCs) to which it binds. Discovery of the Th17 subset and demonstration that IL-17 levels are elevated in RA synovial fluid and that IL-17 plays an important role in mouse models have rekindled interest in T-cell involvement in the chronic phase of RA. Trials of anti-IL-17 antibodies in human RA are under way and will be of great interest.

Cell-cell and cytokine interactions in the perpetuation of inflammation in rheumatoid arthritis

Based on studies involving animal models of RA, both the initiation and perpetuation of TNF and IL-1 production within inflamed synovial tissue, as well as maintenance of an activated phenotype of synovial lining cells and sublining fibroblasts and macrophages for the continued production of these and other critical proinflammatory cytokines, are essential in the pathogenesis of RA. It has been hypothesized that the chronic inflammatory state in RA is maintained by complex interactions and positive feedback loops between cell types resident within and recruited to the synovium. In addition to myeloid and nonhematopoietic cells, T and B cells may play roles in these complex interactions. Interactions between T cells and synovial macrophages and fibroblasts are mediated through CD69, LFA-1/ICAM-1 (CD54), and other ligand-receptor interactions. Previously activated T cells may contribute to the maintenance of chronic inflammation in RA through antigen-independent mechanisms by direct cell-cell interaction with macrophages or fibroblasts (or both) and thereby lead to the augmented production of effector molecules, including TNF and joint-damaging enzymes. For example, membranes from synovially derived T-cell clones have been shown to stimulate the production of MMP-1 and PGE₂, but not the inhibitor TIMP-1, in long-term culture.¹⁴⁵

Many of the mediators previously described in this chapter, most notably TNF, IL-1, IL-6, IL-17, prostaglandins, and chemokines, contribute to these feedback loops. For example, IL-18 induces the production of TNF as well as GM-CSF and IFN- γ , by RA synovial macrophages, an effect that is enhanced by IL-15 or IL-12. IL-18 directly activates both synovial macrophages and T cells and has a potent enhancing effect on the production of TNF induced by T cell-monocyte interactions. Figure 94.15 demonstrates interactions between resident FLSs and monocytes/macrophages that produce cytokines, chemokines, and other factors that activate cells in the local environment and maintain the chronic inflammatory state. Adhesion molecules on endothelial cells are upregulated by these products, which leads to further recruitment to the synovium of inflammatory cells expressing the proper chemokine receptors. These interactions could also augment T-cell activation and stimulate B cells to produce antibodies.

Autoantibodies and immune complexes

Since the discovery of RF by Rose and Waaler and the subsequent identification of RF as an autoantibody directed against the Fc portion of IgG, autoantibodies have been thought to play a role in the pathogenesis of RA. Early theories suggested that RF might initiate disease in RA via deposition of immune complexes in the joint, with the subsequent fixation of complement components, the generation of chemotactic factors including C5a, and the influx of inflammatory cells to the joint. In support of this theory, intracellular and extracellular deposits containing both immunoglobulin and C3 have been identified in synovium and on the cartilage surface in patients with RA, and there is evidence of local complement activation in RA synovial fluid. Such deposits could facilitate the recruitment of inflammatory cells and activation of phagocytes. This paradigm had largely been abandoned because RF is not specific for RA. RF is present in some healthy

Fig. 94.15 Schematic showing some of the key cytokines and other soluble factors and the local cellular interactions that mediate rheumatoid synovitis and joint destruction. Cells are recruited into the synovium from the vasculature. Chronic inflammation in rheumatoid arthritis synovium leads to the activation of macrophages and fibroblast-like synoviocytes (FLS), thereby resulting in joint destruction. Dashed lines depict either movement of cells (i.e., transmigration across the vascular endothelium) or differentiation of cells (i.e., differentiation of monocytes into osteoclasts). individuals and in patients with other chronic inflammatory diseases that are not associated with synovitis, and it is absent in about 20% of patients with RA.

However, the notion that autoantibodies and immune complexes play an important role in disease pathogenesis has been reinvigorated by the discovery of ACPA, the demonstration that the B cell-depleting antibody rituximab is an effective treatment of RA, and the finding that immune complexes or antibodies binding to endogenous components of cartilage initiate disease in rodents that is similar in many respects to human RA.^{121,146}

Lessons from treatment of human rheumatoid arthritis

Treatments that are effective in reducing synovial inflammation in RA can provide essential confirmation that particular cells or mediators remain important in chronic RA. Although detailed mechanisms can only be proposed from mouse models or *in vitro* studies, any theory of the pathobiology of RA must incorporate the following:

- **TNF.** Relevant ancillary findings include the demonstration that synovitis often improves and that clinical relapse occurs in most patients in whom treatment is stopped. Thus, TNF is a particularly important component of synovitis, but the driving force behind TNF production remains intact.
- **IL-1.** IL-1Ra may not be as effective as TNF blockade, but the significant improvement found in controlled trials demonstrates that IL-1 is important in human RA, though perhaps not as critical as it is in mouse models.
- **IL-6.** The rapid time course of improvement with therapies directed against IL-6 suggests that it acts in the synovium rather than through inhibition of antibody production by B cells. Although blockade of IL-6 reduces the production of C-reactive protein and other acute-phase reactants in the liver, these mediators are thought to be markers of inflammation, not causal in tissues.
- **B cells.** The effectiveness of rituximab (anti-CD20 antibody) shows that B cells play a role in established RA, but it does not prove that they do so through the production of ACPA or other antibodies. Correlation of clinical improvement and relapse with titers of RF or ACPA varies among patients.
- **CD80/86 (B7-1/B7-2).** These co-stimulatory markers expressed on the surface of macrophages, DCs, and B cells are important for the activation of T cells that are concurrently being stimulated through their antigen receptors. The clinical effectiveness of abatacept argues that

Fig. 94.16 Dotted arrows reflect pathways that are plausible but for which no detailed information is available, such as the origins of autoimmunity, the source of initial activation of innate immune cells in the synovium, and the possible contribution of activation of innate immune cells to the initiation or amplification of autoimmune responses. RA, rheumatoid arthritis.

co-stimulation of T cells remains important in established RA, but an alternative explanation is that this soluble receptor has direct effects on cells bearing CD80/B7.

Unifying hypothesis

A unifying hypothesis for the pathogenesis of RA must attempt to incorporate information obtained from both human RA and animal models of disease. What seems clear is that RA can best be conceptualized in stages that include disease initiation, establishment and maintenance of chronic inflammation, and destruction of joint tissue (Fig. 94.16), the latter two of which certainly coexist temporally. The event or events that initiate RA are likely to be distinct from those responsible for the establishment and perpetuation of chronic inflammation in the synovium, and destruction of joint

Fig. 94.17 The early phases of the pathogenesis of rheumatoid arthritis (RA) are speculative but probably involve initiation of autoimmunity and activation of the innate immune system (stage I) and amplification of autoimmunity (stage II). These events take place both systemically and within the joint. The pathogenic events in the joint-based chronic inflammatory phase (stage III) are better established. The contributions of immune complexes, antigen-reactive T cells, and antigen-independent T cells probably vary among patients. Tissue destruction (stage IV) coexists temporally with chronic inflammation (stage III). Changes in the number and activity of various cell types over time in the pathogenesis of RA are depicted in the bottom panel, with events depicted in stages I and II being speculative. Ab, antibody; FLS, fibroblast-like synoviocytes; ICs, immune complexes; Mφ, macrophages; Nφ, neutrophils.

structures proceeds by distinct mechanisms that are driven by chronic synovial inflammation. Several possible contributors to RA at these different stages are shown in Figure 94.17.

CONCLUSION

Tremendous progress has been made in understanding the pathogenic mechanisms involved in RA, particularly with regard to those involved in

the chronic phase of this disease. Out of this work have come new and effective targeted therapeutic interventions that have benefited patients with RA, as well as new concepts for future therapies. However, many questions are still unanswered, especially with regard to the initiating events in RA and the exact pathway involved in the establishment of chronic disease. The inroads that have now been made in both the clinical and basic science arenas has certainly set the stage for further investigation and a clearer understanding of these mechanisms in the future.

Evaluation and management of early inflammatory polyarthritis

■ KLAUS P. MACHOLD

- Early institution of disease-modifying antirheumatic drug (DMARD) therapy for persistent or destructive arthritis such as rheumatoid arthritis can prevent joint damage and long-term disability.
- Early recognition of an unfavorable prognosis is a prerequisite for mitigating the consequences of persistent or destructive arthritis with the early institution of DMARD therapy.
- Differential diagnostic support comes from the number of involved joints, duration of symptoms, and the presence of serologic markers such as acute-phase reactants and autoantibodies.
- The American College of Rheumatology/European League Against Rheumatism 2010 classification criteria for rheumatoid arthritis support early diagnosis.
- Early referral of patients with synovitis to the rheumatologist is a prerequisite for early diagnosis and therapy.

THE CONCEPT OF EARLY POLYARTHRITIS

Many inflammatory rheumatic diseases have a chronic course, sometimes spanning decades. From this perspective, the “early” period of arthritis was assumed to last up to several years.¹⁻³ Research involving early arthritis patient cohorts, however, has demonstrated a remarkably short period during which arthritis, in particular, rheumatoid arthritis (RA), may be regarded as “early.”^{2,4,5} It has been implied that interventions such as DMARD treatment would have a much greater effect than would therapy initiated at a later time during the “disease career.” This period has also been named the “window of opportunity” (Fig. 95.1).

Among the (chronic) inflammatory arthritides, RA is considered the most problematic because of its characteristics of joint destruction, functional impairment, disability, and premature mortality.⁶ In addition, other destructive arthritides, most notably psoriatic arthritis, may have similar outcomes.⁷ Retardation of progression or prevention of destruction is possible in both early and later stages of disease^{8,9} by using glucocorticoids, “conventional” DMARDs, biologic agents, or combinations thereof.

Studies on synovial cytokine patterns in patients with early arthritis¹⁰ support the hypothesis that the early months of (rheumatoid) arthritis are characterized by a pathophysiology different from that in later stages. This suggests that the pathogenetic events may change in the course of the disease. These observations are corroborated by clinical studies in which remission was more frequent in RA patients with a disease duration of 4 months or less than in those with a longer duration.¹¹ Likewise, delayed radiologic progression was demonstrated if DMARD treatment was instituted early after symptom onset as opposed to delayed therapy (see meta-analysis¹²). In contrast to these observations, other studies comparing early (symptom duration <1 year) and established RA did not demonstrate any differences between early and long-standing disease, both in the composition of cellular infiltrates and in cytokine expression in the synovium.^{13,14}

Because damage accumulates in the chronic destructive arthritides, it is also possible to define a disease stage as “early,” in which this damage has not yet occurred. Thus the criterion is not a time threshold, which has to be somewhat arbitrary, but the opportunity to preserve joint integrity by timely intervention. In clinical practice, most rheumatologists now define “early RA” as disease with a duration of less than 3 months.¹⁵ It has been hypothesized, however, that the threshold for an optimal treatment response

may be even shorter, about 8 weeks.¹⁶ In any case, if destruction has occurred, immediate institution of effective treatment is mandatory to delay the pace of further damage.

This pace of damage varies substantially. In the majority of RA patients in whom erosive disease developed, it did so within the first year after the onset of symptoms, and approximately 75% of the patients had erosions at 2 years.^{17,18} These findings underscore the necessity to consider effective treatment well before the first year of symptoms has elapsed. On the other hand, a sizable minority of patients with overt synovitis had relatively benign arthritis with self-limited disease or little, if any damage.^{18,19} Likewise, progression patterns in patients in whom destruction or erosions develop are quite variable.²⁰ Sharp and colleagues²¹ suggested that the pace of damage slows down after a longer duration. However, this slowing was only modest and did not appear before the third decade after onset of the disease. At this time a substantial proportion (≈20%) of the joints of these patients already showed “maximum erosion scores.” This observation further supports the requirement for DMARD treatment as early as possible to prevent this catastrophic outcome.

CRITERIA FOR EARLY ARTHRITIS

Patients with arthritis have substantial variability in clinical as well as laboratory or imaging abnormalities.^{20,22} Well-validated criteria to differentiate groups of patients with arthritis at this stage currently do not exist. Classification criteria for “established” RA²³ (as well as for psoriatic arthritis, osteoarthritis, seronegative spondyloarthritis, and other such conditions) were developed for clinical research and are not intended primarily for diagnosis. Rather, they should be used to identify groups of patients with a given disease as clearly as possible and to standardize the characteristics of these patients for clinical studies. Evaluation of an individual patient early in the course of disease must capture many more features of the clinical picture. These features are mandatory for further diagnostic and therapeutic decisions. In addition, given the inherent variability of most arthritides that may have similar clinical manifestations at the onset, prognostication is important for both the physician and patient to select the appropriate therapy. With this knowledge in mind, recent efforts have been directed primarily at identifying risk factors to help define “early RA” or, as has been done in developing the 2010 American College of Rheumatology/European League Against Rheumatism (ACR/EULAR) RA criteria,²⁴ patients who would need to be treated with DMARDs (e.g., methotrexate). These criteria for RA are intended to identify the necessity for DMARD treatment rather than “diagnosis” and encompass the pattern of joint involvement (large vs. small, as well as the number of joints), serology (rheumatoid factor [RF] and anti-citrullinated peptide antibody [ACPA]), duration of synovitis, and acute-phase reactants (APRs). Validation of these criteria over the past years has indeed demonstrated superior sensitivity over the 1987 ACR RA criteria, in particular, in early disease. On the other hand, the 2010 RA criteria appear to be less specific. This relatively low specificity points to the importance of a thorough workup of early arthritis to avoid overtreatment or misdiagnosis.

Taking a slightly different approach, the Leiden group has developed a scoring system to predict RA in a cohort with undifferentiated arthritis (i.e., not classifiable according to the 1987 ACR criteria) lasting less than 1 year. The score includes easily determinable clinical and laboratory characteristics (age, gender, distribution and symmetry of arthritis, morning stiffness, tender and swollen joint counts, C-reactive protein [CRP], RF, and ACPA) and yielded positive and negative predictive values in the vicinity of 90%.²⁵ Like the 2010 ACR/EULAR criteria, this score may guide treatment decisions and thus fulfil the requirement of both avoiding overtreatment and

Fig. 95.1 Initiation of disease-modifying treatment leads to retardation of the disease process, although the effects may vary from patient to patient (“low” or “good” response). In a patient showing a “good” response, early treatment may be able to reverse the disease process. This effect may be lost if the same treatment is started later.

initiating (even very aggressive) treatment in patients in whom RA is highly likely to develop.

CLINICAL DETECTION OF SYNOVITIS

Arthritis is usually painful; conversely, joint pain does not always correspond to synovial inflammation. Swelling—the hallmark of synovitis—may be subtle or hidden beneath muscle or bone (hip, shoulder) or subcutaneous fat (obesity). This causes considerable uncertainty in the clinical assessment of synovitis, with high interobserver variability. Higher sensitivity for synovitis may be achieved by ultrasonography.^{26,27} However, this technique is still not universally available and is time-consuming and costly. Therefore one still needs to rely on clinical examination. At least for the purpose of evaluating joints longitudinally, this should be done in a “standardized” way. The EULAR has issued an illustrated guidebook that offers instructions on joint examination.²⁸ Because pain may be present even if joint swelling is subtle, a positive metacarpophalangeal (MCP) or metatarsophalangeal (MTP) joint compression test (Gaenslen test) offers additional evidence for MCP and MTP arthritis. A positive compression test provides a major contribution to diagnostic algorithms in early arthritis and is present in more than 60% of the patients in whom RA will be diagnosed. Stiffness after rest (frequently referred to as “morning stiffness”) of long duration (more than several minutes) is another typical symptom of joint inflammation. The 1987 RA classification criteria require a duration of at least 1 hour. The stiffness associated with osteoarthritis is typically much shorter. Therefore morning stiffness lasting longer than 30 to 45 minutes may be seen as characteristic of an inflammatory joint disease.²⁵

Many patients whose arthritis will subsequently be diagnosed as RA have low numbers of swollen or tender joints at onset of the disease or at initial physician consultation. In one study involving a very early arthritis cohort, more than 25% of the individuals in whom erosion developed within 1 year had 5 or fewer swollen joints on a 28-joint count at initial evaluation.¹⁸ In another study, patients with early arthritis in whom RA developed had a median of 4 swollen joints and more than 25% had fewer than 4 tender joints on a 44-joint count. In recognition of the implications of these observations, a EULAR task force recommended consideration of early RA even with only one persistently swollen joint.²⁹ Nevertheless, the proposed algorithms for early detection of RA,^{25,30} as well as the ACR/EULAR criteria for RA, weigh polyarthritis more than monoarthritis or oligoarthritis.

EVALUATION AND DIFFERENTIAL DIAGNOSIS OF EARLY ARTHRITIS

Arthritis occurs in many diseases, such as metabolic, degenerative, infectious, and neoplastic disorders. In evaluating arthritis patients, special attention should be directed to the history, to extraarticular signs of disease and the pattern of joint involvement, and to serologic and imaging studies.

In light of the lack of validated recommendations regarding which studies should (or need not) be performed in early arthritis, clinicians may adhere to either of two sets of recommendations. One of these³¹ suggests rapid referral to a rheumatologist in the event of clinical suspicion of RA. According to this guideline, such suspicion should be supported by three characteristics: three or more swollen joints, positive MCP or MTP compression test, and morning stiffness lasting longer than 30 minutes. The other expert panel recommended referral of patients with one or more swollen joint within 6 weeks of the onset of symptoms to a rheumatologist. Careful history taking and clinical and laboratory examinations to exclude other diseases were also suggested. It was emphasized that the probability of persistence increases with the number of swollen and tender joints, with the presence of APRs, and with autoantibody (RF, ACPA) levels; radiographs should be taken to reveal erosive disease.^{24,29}

History and extraarticular clinical signs

Transient arthritis (frequently caused by viral infections) is usually self-limited and thus easily differentiated from RA. Therefore in patients whose arthritis has been present for only several days (up to a few weeks), it may be sufficient, in addition to clinical joint examination, to take a thorough history with special attention directed to exposure to infectious agents (such as contact with people suffering from a rash or fever); preceding infection, rash, or fever in the patients themselves; weight loss; or previous arthritis episodes (such as may occur with crystal-induced arthritis).

Once the duration of arthritis exceeds a few weeks (the threshold most likely lying between 6 and 12 weeks), the differential diagnosis becomes much broader. The differential diagnoses encompass forms of seronegative spondyloarthritis such as reactive arthritis, ankylosing spondylitis, arthritis associated with inflammatory bowel disease, and psoriatic arthritis. In addition, sarcoidosis with arthritis (Löfgren syndrome), connective tissue diseases, rheumatic fever, gout and pseudogout, and osteoarthritis with inflammatory activation are part of the differential diagnostic list. Thus the examination and history should focus on signs of psoriasis (or patients may have a relative with psoriasis), urogenital or gastrointestinal infection, and “inflammatory” back pain. Extraarticular involvement (eyes, mucous membranes, skin) may be subtle and needs to be sought and inquired about. Erythema nodosum may be a sign of sarcoidosis or inflammatory bowel disease, and the arthritis frequently involves the ankle joints symmetrically. In sarcoidosis, typical changes may be present on the chest radiograph; inflammatory bowel disease may be revealed by upper or lower gastrointestinal endoscopy. The rare connective tissue diseases generally show additional clinical manifestations such as myalgias, skin changes (e.g., an ultraviolet light–induced rash, alopecia, sclerosis, telangiectases, Raynaud phenomenon, and others), lymphadenopathy, and manifestations of internal organ involvement. A history of an untreated upper respiratory tract infection (e.g., tonsillitis) may be suggestive of rheumatic fever (or reactive arthritis if the time between the infection and the arthritis is less than 1 or 2 weeks). The characteristic history of crystal arthropathies (including an acute onset of gout after heavy meals or alcohol intake, immobilization, chemotherapy, and preceding episodes of a similar arthritis) is usually diagnostic.

Patterns of joint involvement

Chronic arthritis may show a number of more or less distinct “joint patterns” (Fig. 95.2). This has also been recognized in development of the aforementioned algorithms for risk stratification. Monoarthritis or oligoarthritis (i.e., involvement of two to four joints), though regarded to be a sign of less aggressive disease, may nevertheless represent the initial manifestation of a chronic destructive arthritis. Hand involvement, in particular, is considered to confer a high probability of destructive arthritis. Arthritis mostly in large joints, asymmetric patterns, and early spinal symptoms may be indicative of seronegative spondyloarthritis. In addition, inflammatory/active osteoarthritis of the hands may be manifested as oligoarthritis or polyarticular arthritis, albeit usually with clinically detectable preexisting bony proliferation (Bouchard or Heberden nodes). Although these patterns are sometimes quite characteristic and may be diagnostic (e.g., psoriatic skin or nail lesions), exceptions and “overlap” manifestations (e.g., development of classic seropositive RA in an individual with preexisting Bouchard nodes) occur frequently.

Laboratory and imaging studies

In a patient with early polyarthritis, careful history taking and clinical examination with special attention paid to synovitic swelling and its distribution may allow a preliminary classification and thus an appropriate

Fig. 95.2 (a) "RA pattern." In rheumatoid arthritis (RA), symmetric involvement of small joints (in particular, the hand and feet joints) is considered characteristic. Involvement of larger joints and the temporomandibular joints, however, may also occur. "Symmetry" is not always absolute; in particular, involvement of "joint regions" such as the "metacarpophalangeal joints" or "proximal interphalangeal (PIP) joints" rather than individual joints is observed. The distal interphalangeal (DIP) joints are usually spared. (b) "PsA pattern." Psoriatic arthritis (PsA) typically affects joints in a "longitudinal" ("ray," left side) or "transverse" (right side) pattern. DIP involvement is found, in contrast to RA. In addition, involvement of the axial joints (e.g., sacroiliac joints, frequently asymmetric) is common. Inflammation of periarticular soft tissues and enthesitis (inflammation of insertions of tendons or ligaments) together with skin changes and arthritis may lead to dactylitis, the so-called sausage digits (as on the right second toe in the panel). (c) "ReA pattern." Reactive arthritis (ReA) is typically a monoarthritis or oligoarthritis with predominance of large joints (mostly of the lower extremities) or sacroiliitis. (d) "AS pattern." Inflammation of the joints of the axial skeleton and, in particular, symmetric sacroiliitis, is the hallmark of ankylosing spondylitis (AS). In addition, enthesitis such as in PsA and large-joint involvement may occur. (e) Osteoarthritis of the hands is characterized by bony enlargement (osteophytes) of affected joints, which are frequently the second and third DIP or PIP joints, as well as the first carpometacarpal joint. In affected joints, inflammatory activation with bony destruction may occur and thus make differentiation from RA or PsA difficult.

estimate of the risk for chronic or destructive/disabling disease. Laboratory and imaging studies, however, not only provide additional information related to this risk but may occasionally also show unexpected results, such as evidence of crystal deposits on radiographs or ultrasound or high-titer antinuclear antibodies in a patient with symmetric polyarthritis of the hands. Therefore all classification, stratification, and diagnostic criteria also include recommendations to perform a minimum set of laboratory investigations, as well as imaging studies. In addition, if the clinical "index of suspicion" is high enough, extended laboratory investigations (e.g., screen for antinuclear antibodies, infections, metabolic disease, and genotyping, such as for HLA-B27 and other genetic traits) may be justified. Most criteria recommend performing tests for APRs and for RF and ACPA.

RF, an antibody specific for IgG, is known to be one of the characteristics of RA and is part of almost all RA classification criteria. Between 46% and 75% of patients with early RA test positive for RF.^{18,32} However, RF is not pathognomonic for RA and frequently occurs in those with connective tissue diseases, hematologic and solid neoplasms, and chronic infections, as well as in healthy individuals, mostly in low titer.³³ High-titer RF (>50 IU/mL), in contrast, has been shown to be highly discriminative between RA and non-RA in patients with early arthritis.³⁴ More recently, ACPAs have been reported to occur relatively specifically in RA³⁵; ACPAs are found in the sera of approximately 50% of patients with early arthritis that is subsequently diagnosed as RA and may be present even before the onset of symptoms. Even more importantly, RF or ACPA (or both) can give prognostic information: they are highly predictive of erosive disease and associated with more rapid progression of joint destruction.^{18,35} Moreover, RF is associated with persistence of arthritis.

In addition to these autoantibodies, elevated APRs are another, albeit nonspecific hallmark of early inflammatory arthritis. Patients with early arthritis destined to suffer from RA usually have higher APRs, such as CRP or the erythrocyte sedimentation rate, than do those in whom RA does not develop.²⁵ Characteristically, in the seronegative spondyloarthritides, APRs are less elevated. However, considerable variability between patients and broad overlap make such distinction difficult for individual patients. Moreover, initially normal or negative tests for APRs do not rule out later evolution of erosive disease. On the other hand, joint damage in early RA increases with increasing APRs.¹⁸

Because the genetic background of RA, as well as reactive arthritis, ankylosing spondylitis, systemic lupus erythematosus, and other rheumatic diseases, is quite characteristic, at least in white populations, it is tempting to

use genetic tests for the differential diagnosis. However, the cost of accurate analyses, as well as the complexities of the genetic influences on a given individual's arthritis, currently precludes the use of these tests for routine diagnosis or prognostication.

At present, the only standard technique for visualizing the changes associated with destructive arthritides is conventional radiography (projection radiography). Unfortunately, this technique is notoriously insensitive to small and early changes.²⁶ Magnetic resonance imaging (MRI) and ultrasonography may allow earlier detection of erosions.³⁶ In addition, if the symptoms raise suspicion for shoulder, hip, or spine involvement (e.g., sacroiliitis in psoriatic arthritis or ankylosing spondylitis), MRI is currently probably the most accurate imaging method.

It is also important to recognize that the experience of the reader determines the accuracy of the radiographic diagnosis. Thus only a specialist (radiologist, rheumatologist) experienced in assessing RA radiographs should perform the reading. The presence of erosions, which occur in a majority of RA patients, is very characteristic, albeit not to be expected in the very early stages of the disease. Occurrence of radiographic erosions early after the onset of symptoms is indicative of RA³⁰; however, at a mean of 8 weeks after the onset of arthritis, these changes are found in less than 10% of patients.¹⁸ Therefore this is not a characteristic of early RA. More importantly, the very aim of early diagnosis and treatment is prevention of (possibly irreversible) joint destruction. Thus the diagnosis needs to be made before the appearance of joint destruction.

PROGNOSTICATION IN EARLY ARTHRITIS

The major purpose of diagnosing a disease in a patient is to guide treatment decisions on the basis of prognosis. This prognosis, in turn, determines the timing and intensity of treatment. These treatment decisions determine the frequency of reassessment and follow-up. From the patients' view, the prognosis will also determine the risk involved in taking potentially toxic drugs or undergoing unpleasant or time-consuming treatments such as wearing splints, exercising, or physical therapy. Early prognostication should identify patients who may benefit most from therapeutic intervention and separate them from individuals in whom possibly toxic treatment might cause more harm than benefit. The improved sensitivity of the 2010 ACR/EULAR criteria may help guide these decisions, particularly when differential diagnoses are carefully considered.

TREATMENT OF EARLY ARTHRITIS

Nonsteroidal antiinflammatory drugs and nonmedicinal therapies

Up to 60% of all patients with early arthritis may have a self-limited or benign course.^{19,30} For these patients, only temporary symptomatic relief through the use of nonsteroidal antiinflammatory drugs (NSAIDs), which may also shorten the duration of arthritis, is necessary. NSAIDs do not alter the course or outcome of the arthritis, and long-term use of them may be associated with considerable side effects.

In all forms of arthritis, physical measures such as the application of cold packs or using splints to prevent mechanical irritation have been advocated as temporary or long-term measures. Evidence of effectiveness of these measures, however, is still insufficient or even negative.^{37,38} Given the lack of side effects and possible individual benefits, however, most authors recommend the use of these treatments as palliative or adjunctive measures combined with exercises.

Glucocorticoids

Before the threshold of several weeks or a few months for “persistence” is reached, DMARDs may not be appropriate because they are prescribed for longer periods and their toxicities outweigh the risk associated with a self-limited condition. In clinical practice, glucocorticoids are often used, either by intraarticular or intramuscular injection. Alternatively, short courses of oral glucocorticoids may be prescribed in these patients with very early arthritis. In one of the few studies explicitly addressing the issue of treatment of very early (*not* rheumatoid) arthritis, Green and colleagues³ administered a single dose of 120 mg of methylprednisolone intraarticularly or intramuscularly. The results of this open study suggested that this approach is safe and leads to a significant number of disease remissions. More recently, two additional studies explored the value of glucocorticoids for the management of such patients with very early arthritis^{16,39}: the STIVEA (Steroids in Very Early Arthritis) study found a small, though significant benefit of three weekly injections of depot glucocorticoids in a population with early (<12 weeks' duration) undifferentiated arthritis; however, the SAVE (Stop Arthritis Very Early) study, which used only a single injection in a very similar patient population, could not confirm these findings.

Unlike maintenance therapy with oral glucocorticoids, short-term intermittent use of them is considered safe despite limited scientific evidence to underscore this.⁴⁰

Disease-modifying antirheumatic drugs

In persistent early arthritis (i.e., after 6 to 12 weeks), DMARDs, either singly or combined with glucocorticoids, are appropriate and necessary. Glucocorticoids are regarded as both safe and efficacious singly or combined with DMARDs.^{41,42} In this setting, superiority of early initiation of DMARDs over delayed treatment or treatment with NSAIDs alone has been demonstrated conclusively.⁴³ Because the characteristic bone or cartilage destruction of erosive arthritis rarely, if ever, heals^{44,45} and thus damage accumulates over time, these agents will have better effects on outcome the earlier they are started.

As in established RA, methotrexate is regarded as the drug of first choice in view of its favorable risk-benefit ratio. Other DMARDs such as leflunomide, (hydroxy-)chloroquine, or sulfasalazine may be considered in “mild” cases or in patients with contraindications, such as the desire to become pregnant or significant comorbid conditions such as liver or kidney disease. Likewise, at least in patients who at these stages were classified as having RA, a combination of glucocorticoids and DMARDs offered additional benefits in terms of clinical response, as well as radiologic outcomes,^{41,46} although these findings have not been universally reproducible.⁴⁷

More recently, “aggressive” treatment strategies have been proposed that use combinations of DMARDs or the addition of tumor necrosis factor (TNF) antagonists to “conventional” DMARDs for early “criteria-positive”

RA.^{2,32,48,49} In these randomized trials, combination therapies or the addition of “biologic” drugs resulted in outcomes superior to those with less aggressive “conventional” approaches. It is important to mention that some, but not all combinations of (conventional) DMARDs may be superior to using the same DMARDs singly.⁵⁰ Furthermore, an important limitation in interpreting the results of these trials is that all of them included only patients who fulfilled the 1987 ACR RA criteria at the time of inclusion. Thus it remains unclear whether the possibly higher risk associated with more aggressive strategies is warranted, at least in the subset of patients with less destructive disease.

Biologic agents

Biologic drugs are currently licensed only for established RA and after the failure of at least one DMARD. The BeSt (Behandel-Strategieën [Treatment Strategies]) trial revealed that TNF blockade in patients with early RA yields good clinical results, although combination therapy with DMARDs and intermediate-dose glucocorticoids had similar clinical, functional, and radiographic outcomes.⁴⁹ Currently, several trials are testing TNF antagonists for early undifferentiated arthritis with substantial potential for destruction or persistence (such as RF or ACPA positivity or inflammatory arthritis for a minimum duration). These studies are attempting to clarify whether such extremely early intense intervention might substantially and possibly permanently influence long-term outcomes or even prevent the development of “full-blown” RA (etanercept: the EMPIRE [Etanercept and Methotrexate in Patients to Induce Remission in Early Arthritis] and RIVERA [Remission Induction in Very Early Rheumatoid Arthritis] trials, controlled-trials.com-number, International Standard Randomised Controlled Trial Number [ISRCTN] 55428162 and ISRCTN 49682259; infliximab: DINORA [Definitive Intervention in New-Onset Rheumatoid Arthritis] trial, ISRCTN 21272423).

A recent analysis has revealed that the fate of any DMARD therapy, methotrexate or biologic, can be predicted within 3 to 6 months after commencement. Thus starting patients with early RA on a more traditional therapeutic approach and then switching rapidly to another compound may be the most practical strategy.

CONCLUSION

Early inflammatory arthritis represents a challenge in everyday practice. Differentiation should be made as quickly as possible (within several weeks) between relatively benign disease and conditions needing urgent, highly active treatment. In addition, the treatment intensity selected should avoid the excessive risk associated with at least some of the therapies. Because earlier intervention may be more effective before the underlying pathogenic processes are “fully established” and have reached the “autonomous” stage thought to prevail in the later phases of RA, it seems advisable to treat as early as possible, ideally before damage (the visualized destruction of cartilage, bone, or both) has occurred. The only, albeit still unresolved obstacle to early therapy remains early diagnosis or prognostication (or both). In recent years, however, knowledge of risk factors has advanced and criteria for therapeutic decisions have been refined. In particular, certain disease features appear to indicate an unfavorable prognosis: a higher number of swollen joints, a positive Gaenslen test, RF levels of 50 IU/mL or higher or a positive ACPA test, and elevated CRP appear to confer a very high risk for persistent (and erosive) disease. In addition, the presence of erosions on radiographs confirms the destructive nature of the arthritis. Persistence of arthritis for more than 6 weeks and (initial) oligoarthritis accompanied by serologic evidence of inflammation (RF ≥50 IU/mL or ACPAs) are likewise regarded as indicators of a high risk for the development of chronic and destructive joint disease. In all instances, other diseases associated with arthritis should have been excluded. In a patient fulfilling these criteria, prompt DMARD therapy is advisable to prevent further persistence, joint damage, and disability. In addition, expert consensus calls for rapid referral to a rheumatologist in the event of clinical suspicion of persistent arthritis or RA.

Evaluation and outcomes of patients with rheumatoid arthritis

■ DANIEL ALETAHA ■ JOSEF S. SMOLEN

- Assessment of patients with rheumatoid arthritis is aimed at evaluating or prognosticating the disease process or disease outcome.
- The 2010 classification criteria for rheumatoid arthritis were developed jointly by the American College of Rheumatology and the European League Against Rheumatism to allow assessment and timely institution of treatment in patients with very early and established disease.
- Core sets of individual measures of the disease process have been defined and include joint swelling and tenderness, the acute-phase response, pain, patient global assessment, and evaluator global assessment.
- These individual measures can be effectively integrated into composite indices that allow determination of actual disease activity, as well as disease activity states.
- In clinical practice, disease activity (the disease process) is the immediate target of therapeutic interventions, whereas the ultimate goal of treatment is improvement of disease outcomes and health-related quality of life.
- In clinical trials, disease activity states and responses, as well as their time of onset and sustainment, should be reported.
- The typical proxy for disease outcome is radiographic damage, which is a surrogate for the accrued joint destruction and can be assessed by a variety of quantitative scores.
- Impairment of physical function (disability) is another important outcome and can be assessed with questionnaires, typically the Health Assessment Questionnaire, or direct functional performance tests, such as grip strength.
- Physical function is influenced by both disease activity and joint damage; functional disability related to joint damage is currently considered to be irreversible.

INTRODUCTION

Over the past 2 to 3 decades the approach to treating patients with rheumatoid arthritis (RA) has undergone a spectacular evolution that still continues to advance and has led to unprecedented outcomes. It is a consequence of better insight into the natural history of the disease, better understanding of pathogenic pathways, a burst of novel therapies, innovative clinical trial design, recognition of the importance of treatment strategies over and above the mere application of drugs, and the development of tools to assess RA and its progression reliably.¹ It is particularly the latter that has allowed one to comprehend many aspects of the natural and therapeutically modified course of RA, to design elegant clinical trials, and to develop and modify strategic targets in RA therapy. Many of the instruments developed can be applied in clinical practice quite easily, thus signifying the translation of clinical trial results into the reality of daily patient care. In this chapter the various ways of assessing patients with RA are discussed. However, before assessment of RA can be discussed, adequate diagnosis or classification is needed. In this regard, the 2010 American College of Rheumatology (ACR)/European League Against Rheumatism (EULAR) classification criteria for RA have been published.²⁻⁴ In the first section of this chapter a brief overview of these new criteria is presented.

2010 AMERICAN COLLEGE OF RHEUMATOLOGY/EUROPEAN LEAGUE AGAINST RHEUMATISM CLASSIFICATION CRITERIA FOR RHEUMATOID ARTHRITIS

Until 2010, the classification criteria used for RA were those promulgated by the American Rheumatism Association in 1987. These criteria have increasingly been debated in the recent past because of their lack of sensitivity for early disease, given that they had been derived mostly from patients with long-standing, established RA. The joint working group of the ACR and the EULAR therefore aimed to develop new classification criteria for RA that would replace the 1987 criteria. From July 2007 to June 2010 the working group engaged in a three-step procedure that included a data analysis phase involving cohorts with early arthritis, a consensus science phase, and a refinement phase that led to three publications detailing the process and the final criteria.²⁻⁵

As shown in [Table 96.1](#), the 2010 criteria comprise four domains: (1) a joint domain, including the number and type of affected joints; (2) an autoantibody domain encompassing rheumatoid factor (RF) and anti-citrullinated peptide/protein antibodies (ACPAs); (3) a domain of surrogates of the inflammatory response, namely, acute-phase reactants (C-reactive protein [CRP] and erythrocyte sedimentation rate [ESR]); and (4) a domain related to the duration of symptoms. For evaluation of a patient, the highest category within each domain is used and the four respective numbers are added. The maximum possible score is 10, with any score of 6 or higher indicating the presence of definitely classifiable RA. Another way to classify RA based on the same rules is with the use of a tree algorithm, which leads to the same classification results as the numerical approach. Radiographic evidence of erosions may be considered *prima-facie* evidence of RA, and patients can be directly classified as such. A respective algorithm has been put forward,⁶ and the term “erosiveness” has been clarified in this context as at least three joints with a minimum of one erosion each.⁷

The 2010 criteria should be applied to any patient with at least one clinically swollen joint for which another disease is not the most likely cause. A large number of studies have in the meantime been published that investigated the performance and substantiated the validity of the new criteria in different settings. These studies have very recently been summarized in a systematic review of the literature.⁵

These classification criteria, though especially useful for groups of patients entering clinical trials, can help support a clinical diagnosis of RA but cannot replace it. Establishment of a clinical diagnosis by a physician is the most important step before appropriate therapy can be instituted. Thereafter, it is of utmost importance to monitor patients regularly with respect to their disease activity and outcome. These aspects are discussed in the next sections of this chapter.

CONCEPTS

From pathogenesis to measurement

It is currently not possible to capture the cellular and molecular events leading to RA at the site of involvement, such as the joint or lymphatic organs. Even if we could routinely obtain snapshots of the expectedly manifold and heterogeneous interactions of pathogenic cells and molecules, their hierarchy or relative dominance would not yet be evident to us. As a consequence, measurements have to rely on phenomena that are further downstream from these pathogenetic events.

TABLE 96.1
ACR/EULAR classification criteria for rheumatoid arthritis*

	Score
Joint involvement (0-5)^a	
1 medium to large joint ^b	0
2-10 medium to large joints	1
1-3 small joints (with or without involvement of large joints) ^c	2
4-10 small joints (with or without involvement of large joints)	3
>10 joints (at least one small joint) ^d	5
Serology^e (0-3)^f	
Negative RF and negative ACPAs	0
Low-positive RF or low-positive ACPAs	2
High-positive RF or high-positive ACPAs	3
Acute-phase reactants^f (0-1)^g	
Normal CRP and normal ESR	0
Abnormal CRP or abnormal ESR	1
Duration of symptoms^g (0-1)	
<6 wk	0
≥6 wk	1

*Score-based algorithm for classification of an eligible patient (cut point for rheumatoid arthritis: ≥6/10).

^aIndividuals should be scored with these criteria only if at least one serologic test and at least one acute-phase reactant test result is available. When a value for a serologic test or acute-phase reactant is not available, that test should be considered "negative/normal."

^bJoint involvement refers to any swollen or tender joint on examination or evidence of synovitis on magnetic resonance imaging or ultrasonography. The distal interphalangeal joints (DIPs), first carpometacarpal (CMC) joint, and first metatarsophalangeal (MTP) joints are excluded from assessment. Categories of joint distribution are classified according to the location and number of the involved joints, with placement into the highest category possible based on the pattern of joint involvement.

^cMedium to large joints refer to the shoulders, elbows, hips, knees, and ankles.

^dSmall joints refer to the metacarpophalangeal (MCP) joints, proximal interphalangeal (PIP) joints, metatarsophalangeal (MTP) joints 2 to 5, thumb interphalangeal (IP) joints, and wrists.

^eIn this category, at least one of the involved joints must be a small joint; the other joints can include any combination of large and additional small joints, as well as other joints not specifically listed elsewhere (e.g., temporomandibular, acromioclavicular, sternoclavicular).

^fNegative refers to international unit (IU) values that are less than or equal to the upper limit of normal (ULN) for the laboratory and assay; low-positive refers to IU values that are greater than the ULN but less than or equal to three times the ULN for the laboratory and assay; high-positive refers to IU values that are more than three times the ULN for the laboratory and assay. When RF is available only as positive or negative, a positive result should be scored as "low-positive."

^gNormal/abnormal is determined by local laboratory standards.

^hDuration of symptoms refers to patient self-report of the duration of signs or symptoms of synovitis (e.g., pain, swelling, tenderness) in joints that are clinically involved at the time of assessment.

ACPs, anti-citrullinated protein/peptide antibodies; ACR, American College of Rheumatology; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; EULAR, European League Against Rheumatism; RF, rheumatoid factor.

From Aletaha D, Neogi T, Silman AJ, et al. The 2010 American College of Rheumatology/European League Against Rheumatism classification criteria for rheumatoid arthritis. *Ann Rheum Dis* 2010;69:1580-8.

For example, the acute-phase reactant CRP is known to be induced by interleukin-6, which in turn can be activated by tumor necrosis factor, interleukin-1, and other pathways. Thus, CRP and other acute-phase reactants, which can easily be measured in peripheral blood, constitute downstream manifestations of cytokine activation. Likewise, joint swelling is the downstream ("clinical") expression of synovial inflammation and, consequently, the totality of the underlying inflammatory events, not just for a particular segment such as cytokine activation. Another example is joint destruction, which is elicited by osteoclasts on the one hand (bony damage) and chondrocytes and metalloproteinases on the other hand (cartilage damage), both of which are induced during the active disease process. Currently, we are likewise unable to directly visualize this process as it occurs, but radiographic scores constitute the cumulative downstream markers of these events. Novel imaging techniques, such as methods of molecular and cellular imaging, may shift this paradigm upstream in the future and allow earlier detection and measurements.

The previous list could be expanded broadly but was just meant to exemplify the difficulty in depicting the basic pathogenetic pathways and the need to use their downstream expressions, ideally in some kind of combination, to best summarize the basic events, which are currently still enigmatic, at least from the perspective of accurate measurement.

INTERRELATIONSHIP OF DISEASE PROCESS AND OUTCOMES, AND THE ROLE OF THERAPY

Fig. 96.1 Interaction of disease activity, structural damage, and impaired physical function in rheumatoid arthritis. The effects of different classes of therapeutics are indicated in the hexagons. At any point in time for a patient with rheumatoid arthritis, there is also an interaction with the environment. DMARD, disease-modifying antirheumatic drug; NSAID, nonsteroidal antiinflammatory drug.

Validity of assessments

Assessment is all about measurement and its use to characterize attributes of a disease, including its outcome and prognosis. Any measurement used to evaluate aspects of a disease, be it laboratory tests or clinical measurement tools, must comply with a variety of requirements. It should reflect an important aspect of the disease (as judged by investigators, patients, or both), be reliable, be sensitive to change and thus fulfill the fundamental validity criteria, and be practical and easy to use (feasibility).

Disease process ("disease activity") and consequence ("disease outcome")

In the context of the assessment of patients with RA it is essential to bear in mind that RA, like many other disorders, has several facets that need to be captured. The cardinal elements are disease activity and joint damage, which are both reflections of the underlying pathobiology. At the same time they are intimately associated with other important attributes, such as impairment of physical function, reduction in quality of life, extraarticular manifestations, systemic effects on patient well-being, comorbidity, societal and economic aspects, and mortality (Fig. 96.1). It is legitimate to focus on some of these facets more than on others because, first, there is a hierarchy within this diversity; second, they are all intertwined; and third, some are relatively specific for RA, whereas others are common to many disorders. However, all these components must be taken into account when evaluating RA, and each has its inherent complexity.

Process variables reflect the actual pathophysiologic events and thus constitute mostly instant measures of disease activity, such as swollen joint counts or acute-phase reactant levels. Outcome variables measure the long-term consequences (or sum) of the disease process and include joint damage and physical disability.^{8,9} However, many variables constitute mixtures of both, thereby adding another layer of complexity (see Fig. 96.1). Thus, several process variables, when integrated over time, reflect outcome and several outcome measures reflect actual disease activity, at least in part. Impaired physical function or quality of life, for example, will not only be a long-term product of the process but will also result from actual manifestations, such as pain, joint swelling, and stiffness.

Measures of disease activity may therefore be better defined as variables reflecting the underlying events, which can fluctuate rapidly, spontaneously, or with treatment and have the principal potential to normalize. In contrast, measures of disease outcome, even if they may additionally mirror the actual disease process at an individual point in time, reflect an abnormality that may become fixed in the course of the disease and then no longer bears the

potential to improve, let alone normalize. In other words, *outcome* relates to (a varying degree of) irreversibility (with the ultimate worst outcome being death), and *disease activity* relates to reversibility, amenability to interventions, and possible prevention of bad outcomes. The disease process (“disease activity”) and disease outcome are linked by a temporal relationship (see Fig. 96.1). The strength of this link might be predetermined in individual patients, and prognostic markers may help define subgroups of patients (Fig. 96.2).

Effective treatment includes a reversal of the symptoms caused by disease activity and prevention of the natural course of RA, which results in a bad outcome, that is, structural, functional, and all other consequences of the disease. Sometimes, disease activity markers are used as surrogate markers of disease outcome because their presence reflects the future presence of a bad outcome. Here, the concept of prognostication mixes into the mere evaluation process.

Evaluation versus prognostication

An important concept that needs to be derived from the link mentioned between process and outcome is the distinction between evaluation and prognostication. Although evaluation of disease activity at a given time is aimed at improving outcome, that is, changing the prognosis, in practice it is different from the concept of prognostication by measurement of specific markers: a prognostic marker is generally thought to be relatively constant (“fixed”) and therefore relatively consistent if evaluated repeatedly or at different times, whereas an evaluative marker is supposed to vary, especially in the course of treatment, although again some markers may be valuable for both evaluation and prognostication. Evaluative markers are the main content of this chapter. Typical examples of “fixed” prognostic markers are genetic markers, but autoantibodies can sometimes also be regarded as such, given the information provided by their presence or absence at baseline or at the time of diagnosis, although they might still change over the course of the disease. For completeness, the aims and types of prognostic markers are discussed in the following section.

Two questions have historically always been important in this regard: “Will early undifferentiated arthritis evolve into persistent erosive disease?” and “Will severe disease develop in patients with established RA?”

A number of prognostic factors for disease severity have been found, including the presence and titer of autoantibodies such as RF or ACPAs, (early) joint damage, and the HLA-DRB1 shared epitope alleles. The prognostic value of genetic markers for severe, destructive RA probably reflects an indirect relationship that is due to their association with autoantibody production rather than a stand-alone genetic risk factor. However, even the prognostically relevant autoantibodies have the potential—at least in some patients—to improve in levels or turn negative with effective treatment.¹⁰ Similarly, sociodemographic characteristics and behavioral markers can be mentioned here.

Predicting the course of disease in an individual patient is essential for the interaction between rheumatologist and patient and in the context of therapeutic decision-making. Prognostic indicators can be weighted and combined, and algorithms allowing one to recognize patients in whom persistent destructive arthritis will develop among those with early undifferentiated arthritis have been published but need further validation. However, many of the evaluative markers of the disease process, such as joint counts, acute-phase reactants, and others, collected in untreated patients at baseline also have prognostic value.¹¹

Individual measures versus composite indices

Each individual measure of disease activity may relate only to a portion of disease expression. Also, individual patients differ with regard to the features and course of their disease, and even within an individual patient, disease expression may vary during its course. Moreover, each of the surrogates casts particular emphasis on one aspect of the disease, and evaluation of any one of these aspects over time will not allow reliable identification of a patient’s disease activity and response to therapy. In clinical trials, independent evaluation of each variable is afflicted with methodologic difficulties.¹² Composite indices of disease activity overcome these problems^{13,14} by allowing more consistent follow-up of patients in clinical practice, which will improve outcomes of the disease (Fig. 96.3). In addition, patients’ compliance will be improved by enhanced understanding of the treatment targets, which can be expressed by a single number. In clinical trials, sample size requirements will be reduced by having more power provided by a pooled index.

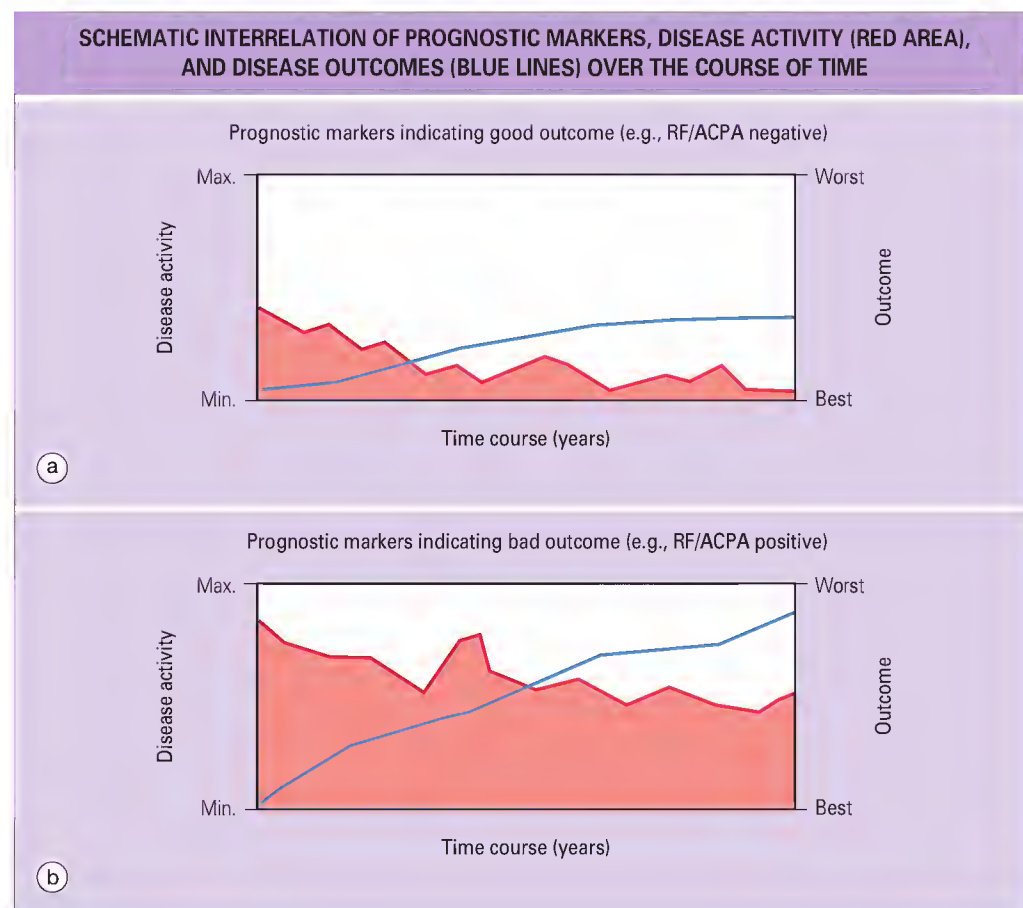

Fig. 96.2 (a) Example of a patient with good markers. (b) Example of a patient with bad markers. ACPA, anti-citrullinated peptide antibody; RF, rheumatoid factor.

Fig. 96.3 Integration of individual variables into composite indices has beneficial effects in clinical practice and clinical trials. CRP, C-reactive protein; EGA, evaluator's assessment of global disease activity; ESR, erythrocyte sedimentation rate; GH, global health; PGA, patient's assessment of global disease activity; SJC, swollen joint count; TJC, tender joint count.

Definition and evaluation of treatment targets in clinical practice

It is of paramount importance that effective treatment be started in the very early stages of the disease.^{15,16} Once therapy is instituted, a clear therapeutic target needs to be defined. It has become evident that adapting therapy to a predefined target value of a disease activity index (e.g., low disease activity) is by far superior to an unstructured change in treatment.^{17,18} Likewise, the lower the disease activity state and the earlier it is achieved, the less destructive the joint damage will be.¹⁹ Thus, the use of dynamic treatment strategies aimed at a predefined goal is one of the most recent innovative steps.

Importantly, the goal should be to reach a certain level or state of disease activity rather than achieve a particular change ("response") from baseline. Respective evidence comes from secondary analysis of clinical trial data in which patients with ACR 50% or 70% response rates (see later) had worse radiographic outcomes if they achieved only a moderate- rather than a low-disease activity state or remission²⁰; additional evidence comes from patient-reported outcomes in observational studies in which patients judge their disease to have undergone major improvement only if a low- to moderate-disease activity state had been attained, irrespective of baseline disease activity.²¹

Given that the long-term response to therapy can already be predicted 3 to 6 months after initiation,²² therapy should be switched or adapted if no improvement is seen within 3 months or if the predefined goal is not achieved within 6 months. Consequently, especially after the start of treatment or with active disease, follow-up examinations using the appropriate instruments for assessment of disease activity need to be performed at least every 3 months to decide on continuation or adaptation of treatment. Outcome measures such as joint radiographs are needed less frequently, although functional evaluation may complement the insight gained from assessment of disease activity.

Assessment strategies in clinical trials

Although in clinical practice the ultimate goal is to measure each individual patient's disease activity most accurately, this focus shifts a little bit when it comes to measuring disease activity in clinical trials. The purpose of clinical trials is to show that interventions work on the *group* level when compared with another group treated differently. For clinical trial reporting, core set variables have been defined internationally,²³⁻²⁵ and criteria for improvement have been established.^{26,27} More recently, the ACR and EULAR have developed a minimal standard of core information to be provided when reporting

BOX 96.1 EULAR/ACR RECOMMENDATIONS FOR REPORTING CLINICAL TRIAL RESULTS IN RHEUMATOID ARTHRITIS*

Preamble

Several domains are important in reporting clinical trials: disease activity, function, and damage. For each of these domains, response and state should be assessed and reported in clinical trials when appropriate.

However, the following recommendations deal specifically with *disease activity*.

- Each trial should report both the disease activity response and disease activity states.
 - Response*: ACR and EULAR response criteria.
 - States*: Continuous composite indices of disease activity with cut points to define various disease activity states; they include DAS/DAS28, CDAI, and SDAI. Appropriate descriptive statistics of the baseline, the endpoint, and change in composite indices should be reported.
- Each trial should report the appropriate descriptive statistics of the baseline, the endpoint, and change in the single variables included in the core set.
- Each trial should report the baseline disease activity levels, which could have relevance when interpreting the results.
- Each trial should report the percentage of patients achieving a low-disease activity state and remission.
 - Definitions that should be used for low disease activity include cut points for low disease activity for DAS/DAS28, CDAI, and SDAI and MDA.
 - Definitions that could be used for *remission* include preliminary ARA remission criteria and respective cut points for DAS/DAS28, CDAI, and SDAI.
- Each trial should report the time to onset of the primary outcome (a particular response or a certain disease activity state).
- Each trial should consider and report the sustainability of the primary outcome (as opposed to evaluating it at a single predefined point during the trial).
- Each trial should report on fatigue.

*For the definition of the various instruments, please see the respective sections in the chapter.

ACR, American College of Rheumatism; ARA, American Rheumatism Association; CDAI, Clinical Disease Activity Index; DAS28, 28-Joint Disease Activity Score; EULAR, European League Against Rheumatism; MDA, moderate disease activity; SDAI, Simplified Disease Activity Index. Adapted from Aletaha D, Landewe R, Karonitsch T, et al. Reporting disease activity in clinical trials of patients with rheumatoid arthritis: EULAR/ACR collaborative recommendations. *Arthritis Rheum* 2008;59:1371-7; and Aletaha D, Landewe R, Karonitsch T, et al. Reporting disease activity in clinical trials of patients with rheumatoid arthritis: EULAR/ACR collaborative recommendations. *Ann Rheum Dis* 2008;67:1360-4.

on clinical trials; such information includes baseline *and* endpoint data for the core set variables and composite scores, *as well as* response *and* state data, including proportions of patients with low disease activity and in remission (Box 96.1).²⁸ Inherent in these recommendations is the goal of achieving trial reporting in RA that is consistent across clinical trials rather than varying depending on selected endpoints and that is also meaningful from the clinical rheumatologist's perspective rather than being meaningful merely because of the statistical properties of a specific measure.

INSTRUMENTS FOR ASSESSING DISEASE ACTIVITY

Joint swelling and tenderness, pain, as well as the global impression of disease activity by the patient and the person evaluating the patient, and laboratory measures of the acute-phase response are regarded as the major (core) variables for assessment of disease activity. These measures have been defined in respective core sets of the various organizations (see later). In addition, a variety of other variables exist, such as morning stiffness, squeeze pain, and fatigue, and deserve being addressed in this context.

Core sets of disease activity variables

In the early 1990s, efforts to select a minimum set of measures to be included for assessment of disease activity in RA clinical trials arrived at similar results across various international organizations. The core sets comprise tender and swollen joint counts (TJCs, SJC), patient assessment of pain and global disease activity (PGA), evaluator assessment of global disease activity (EGA), acute-phase reactants (CRP, ESR), physical function, and radiographic assessment of joint damage. Derivation of these measures was driven by data, was supported by consensus, and showed validity in all respects (see Box 96.1). The ACR and World Health Organization/

International League Against Rheumatism core sets were identical and originally called for examination of 66 joints to determine the SJC, examination of 68 joints to determine the TJC, and evaluation of physical function as assessment of disease activity, whereas radiographic changes were the sole outcome measurement. The EULAR core set did not include EGA and used 28 joints for the SJCs and TJCs. Subsequently, the ACR also approved the application of reduced joint counts. Moreover, the EULAR regarded functional assessment as an outcome measure, in addition to joint damage, rather than a measurement of activity. In the context of this chapter, activity measures, damage, and physical function are discussed separately because we believe in the conceptually distinct, though intertwined nature of activity (process), damage (structural changes), and function, with the latter constituting a hybrid measure comprising the two former and more (see Fig. 96.1).

Swollen and tender joint counts

Joint involvement is the fundamental hallmark of RA. Joints are the “organ involved” for the patient and the “organ of interest” for the rheumatologist. It is therefore virtually obligatory to assess the organ joint at every patient visit. Inflammation of the joint leads to soft tissue swelling (synovitis, effusion), tenderness, pain on motion, reduced range of motion, and in the longer term, damage and deformity. Several joint counts and indices have been developed over the decades that differ in the number of joints assessed or in the way that joints are aggregated into joint regions.

The 66/68-joint count assesses, among many other joints, the distal interphalangeal joints of the hands, which are not usually involved in RA

but frequently affected in osteoarthritis and psoriatic arthritis. The 28-joint count excludes these joints, as well as the joints of the ankles and feet, which are often painful and tender for reasons other than RA; also, these regions are often swollen because of comorbid conditions, thus entailing the possibility of misjudgment. Moreover, the 28-joint count frequently captures involved joints and reflects the complete joint count very well. Importantly, however, use of the 28-joint count for assessment of disease activity does not negate the importance of other joints, particularly those of the feet, which clearly need to be evaluated in the course of thorough follow-up. A variety of other joint counts have been published in the literature, some of which are presented in Table 96.2, which has been adapted from a recent review.²⁹ However, the 28-joint count seems to be the most established reduced joint count at present. Indeed, the 28-joint count is simple and fast to assess and has all the validity attributes.

Joint counts differ not only in the number of joints assessed but also by the fact that some (older) scales weight joints by surface area (usually referred to as “weighted” joint counts) whereas other indices weight joints by severity of swelling and tenderness (usually referred to as “graded” joint counts) (see Table 96.2). Some historic joint indices are discussed in the supplement. Importantly, neither do expanded joint counts convey more information than reduced ones nor does weighting or grading provide added value. Instead, interobserver error increases with the use of more complex means of evaluating joint involvement, which is indeed one of the major problems with joint counts. However, within a single observer, joint counts are reliable. This is also the case with self-assessed joint counts, but the differences from assessor-derived joint counts are tremendous; therefore,

TABLE 96.2

patient assessment of joint counts is not recommended³⁰ except in those with no or only a few affected joints (i.e., near remission), in which case self-assessment of recurrent joint activity might be a reliable option.

TJCs and SJCes may run common as well as disparate courses. Although TJCs and SJCes correlate with each other, TJCs correlate with pain and are more sensitive to change. TJCs also correlate with disability. In contrast, SJCes correlate much better than TJCs with progression of joint damage, thus suggesting that they reflect the pathogenetic events typical of RA more accurately. Likewise, SJCes correlate well with acute-phase reactants, but when it comes to states near remission, residual joint swelling appears to be structurally more relevant than residual elevations in acute-phase reactants.³¹

Pain

Pain is a prominent symptom in RA. It is assessed mostly on a 100-mm horizontal visual analog scale (VAS) and typically evaluates the period of the last week. Numerical or verbal rating scales are also used, frequently as 5-, 11-, or 21-point scales (the latter in steps of 0.5). Horizontal and vertical VAS scales are well correlated, but vertical scales tend to produce systematically higher values, although patients' ability to complete a VAS is considerably heterogeneous. In this respect, 11-point numerical rating scales of pain seem to be similarly reliable and responsive but are easier for patients to use. The ACR recommends the use of a 10-cm horizontal VAS with "no pain" at one end and "worst possible pain" at the other, without intermediate categories, or the Likert scale (1 = asymptomatic, 2 = mild, 3 = moderate, 4 = severe, 5 = very severe) to assess current pain in clinical trials.

Patient and evaluator assessment of global disease activity

Global disease activity rated by the patient or the physician (or practically any other third person evaluating the patient, i.e., the "evaluator") is also typically assessed on a 10-cm VAS. In addition to the PGA, sometimes the global health scale is evaluated, which essentially also includes all possible domains of health outcomes that are not directly related to "disease activity." The subjective PGA and the integrative and more objective EGA are usually assessed in combination. Patients tend to rate their disease activity higher than their evaluators do, a systematic difference, which is a good argument for evaluating both in common ("averaging" effect). One reason for this difference might be that patients relate their disease state to their experience with the disease whereas evaluators relate an individual patient's disease status to their experience with all their patients; more likely, however, it is related to the fact that patients inevitably include their pain levels into assessment of their disease activity.³² If the pain levels are related to chronic problems (i.e., not related to disease activity), a discordance with the evaluator global score may be obvious. The responsiveness of measures of global disease activity is good, and such measures discriminate well between different levels of response and treatment groups.

Acute-phase reactants

The most frequently used and most reliable biomarkers for RA are the acute-phase reactants CRP and ESR. Although many other biomarkers, especially proinflammatory cytokines, also reflect the events ongoing in active RA and may even more directly mirror the disease process and response to treatment, they have not been shown to provide information superior to that afforded by acute-phase reactants. Indeed, biomarkers reflecting joint damage or synovial inflammation have not been shown to provide information superior to that conveyed by CRP. The acute-phase reactants, however, correlate well with SJCes, and time-integrated acute-phase reactants also correlate well with radiographic progression. However, in composite indices, acute-phase reactants, especially CRP, add only little information (unless they are heavily weighted such as in the DAS28 [see later]), although they increase the content validity of a score by encompassing an "objective" laboratory measure. Moreover, acute-phase reactant levels are also prone to elevations because of other reasons, such as infection, whereas they are normal in many patients with RA at initial evaluation. When it comes to radiographic progression, normalization of the acute-phase response is not as important as achieving absence of any joint swelling.³¹

Composite indices of core set measures

Composite measures of disease activity are able to capture the spectrum of the disease despite its variations. This is relevant because RA has very heterogeneous manifestations across individuals and even within individuals when assessed longitudinally. Many features of disease activity provide overlapping information, but they are still complementary in some respects. Thus, evaluation of any single measure does not allow sufficiently accurate

determination of the present level of a patient's disease activity or response to therapy. In addition, it is difficult to decide which single measure should be used as a disease activity marker in clinical trials, and moreover, independent evaluation of all variables is associated with methodologic problems.¹² Composite indices are a solution to this problem because they provide a single result but are based on a combination of several measures. The indices differ in terms of what they measure (i.e., current disease activity or change) and their scales (e.g., continuous or ordinal). Continuous measures usually allow one to determine an "absolute" value of disease activity at any point in time or—by virtue of established cut points—the current disease activity state, such as remission. Historic composite scores are discussed in the supplement.

The composition of various composite scores is shown in Table 96.3. The *Disease Activity Score* (DAS) was derived statistically and based on physicians' decision to start or stop treatment with disease-modifying antirheumatic drugs (DMARDs). This was related to states of high and low disease activity, respectively.³³ The DAS therefore uses a complex formula that involves transformations and weighting of variables (see Table 96.3). The original DAS used the graded Ritchie Articular Index to evaluate joint tenderness and a 44-joint SJC (see Table 96.2), whereas its modification, the DAS28, uses condensed 28-joint counts.³⁴ The DAS and DAS28 have also been modified to include CRP instead of ESR (DAS-CRP and DAS28-CRP) or to exclude assessment of global health (DAS-3 and DAS28-3), and cut points for disease activity states have been derived (Table 96.4). For the DAS28, cut points between high disease activity, moderate disease activity, low disease activity, and remission are 5.1, 3.2, and 2.6, respectively. Although with high ranges of composite indices the probability is high that all or most components contribute fairly equally to the result, the situation is different in the lower ranges of the DAS/DAS28. In this case a single component, such as an acute-phase reactant or a patient's assessment of disease activity, may dominate the score and be misleading of overall disease activity. In fact, many patients in DAS28 remission may have significant residual disease activity, especially a high number of swollen joints, because of the low weight of swollen joints in the formula.³⁵ Moreover, because the ESR is strongly weighted, small changes in the ESR, even within the normal range, may lead to categorization of patients as being in remission even though they have many swollen joints. Therefore, in states of low disease activity, a separate look at the contributing components may be worthwhile before drawing therapeutic conclusions. Given the complex formulas of the DAS and DAS28 and the computational complexity in calculating them, simpler indices were sought and developed.

The variables of the *Simplified Disease Activity Index* (SDAI)³⁶ (see Table 96.4) were selected from the core set of the ACR and the EULAR.^{23,24} It was the first index for RA to use a linear sum of variables that were untransformed and unweighted, a concept based on previous studies on reactive arthritis. The SDAI has been widely validated, and definitions of states of remission and of low, moderate, and high disease activity have been elaborated.³⁷ The SDAI, DAS, and DAS28 require the availability of an acute-phase reactant (CRP or ESR), which frequently precludes immediate assessment because of the unavailability of laboratory results. However, even in the absence of CRP values, the resulting score comprising the residual SDAI components was shown to have correlational and construct validity, as well as sensitivity to change.³⁶ The statistical rationale and validity of such a clinical index, then named the *Clinical Disease Activity Index* (CDAI), were subsequently shown (see Table 96.4).³⁸ The value of the CDAI lies particularly in allowing the treating physician to make prompt treatment decisions based on actual levels of disease activity. Similar to the DAS28, cut points between the states of high disease activity, moderate disease activity, low disease activity, and remission have been defined as 26, 11, and 3.3, respectively, for the SDAI and as 22, 10, and 2.8, respectively, for the CDAI (see Table 96.4). The SDAI and CDAI both have stringent measures of remission that allow only a maximum sum of two swollen or tender joints (2 + 0, 1 + 1, or 0 + 2, respectively).

A variety of patient-reported questionnaires for evaluation of disease activity in RA have been published. The *Rapid Assessment of Disease Activity in Rheumatology* (RADAR)³⁹ is a brief, two-page, patient self-assessed questionnaire that includes six items (see Table 96.3). RADAR requires expert interpretation of its individual items—or the use of other studies as references—but does not provide a single "total" result. Another instrument developed for clinical practice is the *Rheumatoid Arthritis Disease Activity Index* (RADAI),⁴⁰ a five-item questionnaire (see Table 96.3). The RADAI requires the use of a calculator, and its agreement with scores encompassing physician assessment is low. Both the RADAR and RADAI are rarely used in clinical practice and clinical trials; rather, patient self-assessment of physical function is frequently used. Another series of summary measures based primarily on patient report, called the *Routine Assessment of Patient Index*

Data (RAPID) scores, have been published recently and include three to five of such measures.⁴¹ RAPID-3 includes three patient-reported measures: physical function, pain, and global estimate; RAPID-4 adds a self-reported joint count from the RADAI (see earlier); and RAPID-5 adds a physician estimate of global status. Thus, RAPID does not include a formal evaluator-assessed joint count and includes physical function, which may be partially irreversibly impaired and therefore limited in its sensitivity to change (see later).

Improvement criteria

Assessing improvement with treatment is important in clinical trials, as well as in clinical practice. The term *improvement* incorporates a time component

and implies that disease activity is assessed and compared with baseline activity. In clinical trials the baseline is usually the trial baseline, whereas in clinical practice it is often less clearly defined. Frequently, it will be the start of a therapeutic segment, which can be a visit of a patient to a specific clinic or (more often) the start of DMARD treatment.

Improvement can be assessed by looking at absolute or relative changes from baseline. However, improvement can also be evaluated by looking at whether a patient has achieved a good clinical state. In principle this evaluation does not depend on comparison to baseline and therefore is more feasible in clinical practice. Finally, there is also the option to assess improvement by combining a change with achievement of a particular disease activity state.

An important step in distinguishing between active medication and placebo was the *Paulus* criteria (see supplement). The ACR improvement criteria²⁶ are a modification of the Paulus criteria and have been used widely in clinical trials in the past decade. They require 20% improvement (“ACR20”) in SJCs and TJCs and in three of the five remaining core set variables (patient and evaluator global assessments, pain assessment, physical function, and acute-phase reactant level). These criteria were developed to best discriminate the effects of active drug from placebo in clinical trials. The minimal improvement is a 20% response (ACR20), but the criteria have also been applied to study more profound responses, such as ACR50 and ACR70, although the latter do not discriminate better between placebo and active medication and may even have less statistical power. Similar to the Paulus criteria, the ACR criteria do not consider the starting level of a patient’s disease activity and provide only a dichotomous “yes/no” result. The numerical ACR response, the ACR-N, has been developed to create a continuous scale ranging from 0% to 100%, and it uses the original structure of the ACR response criteria. The readout is the smallest relative improvement in three measures: SJC, TJC, and the median of the five remaining core set variables.⁴² One point of criticism regarding the ACR type of response criteria is the issue of neglecting deterioration (0% is the minimum). In addition, the ACR-N response cannot be assessed over time (area under the curve) since the results may be inflated because of calculation of response in comparison to baseline at every time point. It should be emphasized that an area under the curve analysis of continuous composite indices (cumulative disease activity over time) can be useful for determining differences between treatment groups when rapidity of response is an issue.

A few years ago the ACR response criteria were modified, and the ACR adopted the so-called Hybrid-ACR criteria as its new official response measure.⁴³ The *Hybrid-ACR* is a pseudo-continuous index that is based on the traditional ACR response assessment. To obtain the Hybrid-ACR, first the average percent improvement in the core set measure needs to be determined, but in the case of worsening, the percentage is censored by 100%, even if the respective measure deteriorated by much more. Thereafter, two outcomes are determined: first, the average of the percent changes across all core set measures and, second, the level of traditional ACR response (i.e., ACR nonresponse or ACR20, ACR50, or ACR70 response). The Hybrid-ACR, then, is the first of these two (mean percent change across the core set variables), except if it does not fall within the respective range of the traditional ACR response. In such cases the response is categorized to values of 19.99, 49.99, and 69.99 if the mean core sets are lying above the traditional ACR categories achieved, or they are set to 20, 50, or 70 if the mean core sets are lying below the respective ACR categories. The Hybrid-ACR is therefore a rather complex index with an unusual distribution that has natural peaks at the values mentioned. Its statistical properties have not yet been determined clearly. Although it has been adopted because it discriminates active drug from comparator at the highest level of statistical significance, it has not been a primary outcome measures in major clinical trials to date.

The EULAR response criteria require not only a certain degree of improvement but also attainment of a good (or moderate) disease activity state (Fig. 96.4).²⁷ The EULAR criteria are based on DAS or DAS28 measurements. They classify improvement into no, moderate, or good response. In clinical trials, good plus moderate responses tend to be somewhat higher than the ACR20 response, and a good EULAR response is usually more frequent than an ACR50 response.

Finally, response criteria have recently been introduced for the SDAI and CDAI.⁴⁴ Their development process was based on using the ACR 20/50/70 response criteria as the comparator, and complex statistical methods to derive a comparable SDAI (or CDAI) 50%, 70%, and 85% response were included. Calculation of the SDAI and CDAI response level is a simple relative change from a given baseline, which typically would be the start of a clinical trial or initiation of a new DMARD in clinical practice. For each level it produces a yes/no response similar to the ACR criteria and allows quantification of patients who have reached the respective mark.

Remission criteria

Today’s ultimate treatment goal for RA is remission. At no point during the history of RA have so many patients been able to achieve remission. Remission is regarded as no or only minimal residual disease activity. Remission criteria have historically been complex and required a time frame of presence; however, remission is currently considered a state that can occur at any point in time, whereas remission over a certain period would be regarded as sustained remission.⁴⁵ Likewise, remission on or off therapy is another quality of remission that cannot influence the definition of the remission state.

RESPONSE CRITERIA FOR RHEUMATOID ARTHRITIS BY THE EUROPEAN LEAGUE AGAINST RHEUMATISM (EULAR) BASED ON IMPROVEMENT AND STATE OF THE 28-JOINT DISEASE ACTIVITY SCORE (DAS28)

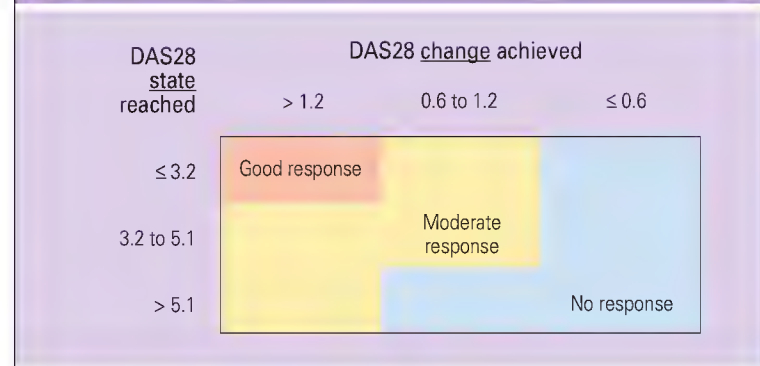

Fig. 96.4 Response criteria for rheumatoid arthritis by the European League Against Rheumatism (EULAR) based on improvement and state of the 28-joint Disease Activity Score (DAS28).

TABLE 96.5

ACR-EULAR provisional definition of remission

Remission definition for clinical trials		Remission definition for clinical practice (no CRP)	
Index-based	SDAI ≤3.3	Index-based	CDAI ≤2.8
Boolean (all at the same time)	SJC ≤1 TJC ≤1 PtGA ≤1 cm CRP ≤1 mg/dL	Boolean (all at the same time)	SJC ≤1 TJC ≤1 PtGA ≤1 cm

CDAI, Clinical Disease Activity Index; CRP, C-reactive protein; PtGA, patient global assessment; SDAI, Simplified Disease Activity Index; SJC, swollen joint count (28 or expanded); TJC, tender joint count (28 or expanded).

Subsequently, remission was defined in terms of the DAS and DAS28 (DAS <1.6, DAS28 <2.6); however, because of the preponderant weight of tender joints and acute-phase reactant levels,³⁵ DAS and DAS28 remission can be accompanied by significant residual disease activity. Recently, the ACR and EULAR addressed this issue in an extensive analysis and provided provisional remission definitions (Table 96.5) that are stringent and do not allow residual disease activity beyond a minimal extent of residual joint swelling or tenderness.⁴⁵

INSTRUMENTS FOR ASSESSING PHYSICAL FUNCTION

Physical function is a central aspect of life for patients with RA and thus a major focus of patient care. Physical function can be regarded as one domain within the wider concept of health status and a key driver of a patient’s quality of life. Improving functional outcomes is therefore a central goal of RA therapy. Physical function can most directly be assessed by subjecting individuals to performance tests. Such tests are often too complex to implement in a broader group of patients or to assess function of only specific body parts, such as hand function. Some of these tests are detailed in the online supplement. In clinical practice, function is most commonly evaluated with questionnaires, which are described in the following text.

A large number of questionnaires can be used to assess physical disability or quality of life in patients with RA. For a comprehensive examination of these questionnaires the reader is referred to relevant review articles.⁴⁶ The most frequently used ones will be discussed briefly. The Medical Outcomes Study Short Form-36 (SF-36)⁴⁷ is the most commonly used generic (i.e., non-disease specific) measure, and it includes physical function as one of its eight scales (domains). From its 36 items, eight subscales, including physical functioning, physical role, pain, and general health, as well as vitality, emotional role, social functioning, and mental health, can be calculated from 2 to 10 items of the questionnaire. Two summary measures, the physical component score (PCS) and the mental component score (MCS), can be

calculated for the first and the latter four, respectively, whereas one item on reported health transition stands alone. Each scale is expressed with values from 0 to 100, and a lower score indicates poorer health. The PCS and MCS are expressed by using norm-transformed domain scores that yield normative values of 50 with a standard deviation of 10 to allow comparison across populations, although such normalization may reduce the degree of potential change. The minimal clinically important difference (MCID) for the PCS is 5 to 10 points in individual domains and 2.5 to 5 points for the MCS domains. As a generic tool, the SF-36 is useful because it allows comparison of patients with different diseases and with the normal population. It is a valid and reliable tool with good psychometric properties.

The Health Assessment Questionnaire (HAQ)⁸ is a more disease-specific functional instrument. The “full” HAQ includes assessment of discomfort, drug side effects, cost, mortality, and the Disability Index (HAQ-DI). Only the latter is in widespread use. The HAQ-DI evaluates the ability to perform activities of daily living. It comprises 20 questions on activities involving the upper or lower extremity (or both), which are organized into eight categories (dressing, rising, eating, walking, hygiene, reach, grip, and usual activities). For each question there is a four-level difficulty scale ranging from 0 to 3 that represent no difficulty (“0”), some difficulty (“1”), much difficulty (“2”), and inability to do (“3”). The final HAQ score is the mean of the highest scores across the eight categories and ranges from 0 to 3, with higher levels indicating more disability. Since its introduction, many modifications of the original HAQ have been published; Pincus and colleagues developed the modified HAQ (MHAQ) to simplify scoring for daily clinical care, although the original HAQ remains the most widely used instrument. In the MHAQ, questions from the original HAQ were reduced to one or two per category, and its total score is also derived by taking the average of the eight categories. In 1999, Pincus and associates introduced the multidimensional HAQ (MDHAQ), which amended the 8-item MHAQ to 14 items.⁴⁸ These additional items improved the floor effect that had been noticed with use of the MHAQ. Because the intervals between scores at different points of the HAQ scale did not translate into similar changes in functional impairment, Wolfe and colleagues recently developed the HAQ-II, in which this psychometric problem has been addressed.

The MCID of the HAQ has been suggested to be 0.22. However, recent studies have shown that the potential for change in HAQ scores may differ depending on the average duration of RA. The amount of underlying damage may reduce the reversibility of HAQ scores in individual patients. Likewise, in highly active RA, HAQ scores vary little with respect to differences in underlying damage because of the great impact of activity on the HAQ, with an average HAQ score of about 1.3 (and up to a mean of 1.9 in trials), whereas in remission, HAQ scores differ considerably but were mostly less than 0.6. Thus, it is important to bear in mind that the HAQ as a measure of functional limitation is determined by both activity (reversible component) and accrued damage (irreversible component). In early stages of RA the HAQ score is usually fully reversible, although this may not at all be the case in very late stages. It has been well established that the HAQ-DI increases with increasing duration of RA because of the accumulated joint damage and even more directly by the fact that over the longer term the correlation between HAQ-DI and radiographic damage increases. It has been observed that over a range of about 20 to 100 points of the radiographic Sharp score or its van der Heijde modification (see later), each point corresponds to a 0.01 irreversible HAQ score.⁴⁹

The Arthritis Impact Measurement Scale (AIMS)⁵⁰ includes nine domains, each of which consists of 4 to 7 questions for a total of 49 questions. Different versions of the original AIMS have been published, including the longer AIMS2 (12 domains and 78 questions) and the shorter AIMS2-short form (5 domains and 26 questions). In one study the AIMS2-SF was shown to reduce completion time while maintaining the properties of the longer AIMS2. Wolfe and colleagues developed the clinical HAQ (CLINHAQ), which in addition to the eight categories of the original HAQ, borrowed the depression and anxiety scales from the AIMS and included five additional VASs and a pain diagram. The Euro-QoL 5-D (EQ-5D) is a simple standardized self-reported questionnaire for use as a measure of health outcome (“health states”).⁵¹

INSTRUMENTS FOR ASSESSING STRUCTURAL PROGRESSION

Scoring of radiographs

Radiographic damage is the hallmark of RA, and it usually progresses over time. Most radiographic scoring methods are based on assessment of the hands and feet, joint areas that are thought to be representative of overall

radiographic damage. Because measurement error is an issue in radiographic scoring, it is recommended that readers be trained and the mean of two independent readers be calculated. If the purpose is assessing structural damage, annual radiographs of the hands and feet are generally satisfactory, but for particular research questions or in early RA, smaller intervals or the inclusion of more joints (or both) might be appropriate. It is still a matter of debate whether radiographs should be read in random or chronologic order because reading radiographs in random order reduces expectation bias (improving the signal-to-noise ratio) but the ability to determine small changes is decreased. A large number of instruments are in use for radiographic scoring and can be categorized into three groups (Table 96.6): (1) instruments assigning a single radiographic grade to a patient (no longer in use; see supplement), (2) those that provide an overall score for a given joint and sum the scores of multiple joints, and (3) those that score two or more features of each joint separately and then sum multiple joints into the radiographic score (by feature or as a total sum of scores on different features).

The most prominent scoring method that combines all features of a particular joint globally is the Larsen method (soft tissue swelling or osteoporosis = 1; erosions of increasing extent = 2 to 5). Standard atlas radiographs are provided for all joints as a comparative means. The method was later modified by Larsen to remove soft tissue swelling and osteoporosis.⁵² In the new method, a score of 1 already required erosions or joint space narrowing to be present. Since its development, the Larsen score has been modified manifold times (see Table 96.6).

The Sharp score⁵³ was the first instrument to include separate scoring for erosions and joint space narrowing (see Table 96.6) as a reflection of bone and cartilage damage, respectively, which may provide independent information. It initially evaluated joints of only the hands and wrists but was further modified by Sharp to enable evaluation of the feet as well (see Table 96.6). A modification of the Sharp score by van der Heijde⁵⁴ also introduced the 10 metatarsophalangeal joints and the interproximal joints of the big toes, whereas some areas of the wrist were excluded because of difficulty assessing them. The Sharp–van der Heijde (SvdH) score is widely used now (Fig. 96.5). In this score, erosions of the feet are scored 0 to 10 (see Table 96.6). Another score that has been used in recent clinical trials is the Genant-modified Sharp score, which assesses fewer joint regions than the Sharp and SvdH scores do, uses a scale of 0 to 3.5 for erosions and 0 to 4 for joint space narrowing, and ranges from 0 to 150 rather than beyond 400 (see Table 96.6). A Simple Erosion and Narrowing Score (SENS) counts the number of eroded joints and the number of joints exhibiting narrowing and sums them. Several other modifications use different joint regions or other features, such as malalignment, in addition to erosion and joint space narrowing (see Table 96.6). In general, the Sharp and the Larsen methods provide similar estimates of radiographic severity, but the Sharp score and its modifications are more sensitive to change.

A single radiograph in conjunction with knowledge of a patient's duration of RA allows estimation of the annual progression rate. This rate integrates an individual patient's history (RA severity and treatment) as a

Fig. 96.5 Separate evaluation of erosions (0 to 5) and joint space narrowing (JSN) (0 to 4) in the joints of the hands and the feet. (Adapted from van der Heijde DM, Van't Hof MA, van Riel PL, et al. Validity of single variables and composite indices for measuring disease activity in rheumatoid arthritis. *Ann Rheum Dis* 1992;51:177-81.)

TABLE 96.6

Radiographic scoring methods for rheumatoid arthritis

	Level of assessment	Scale/joint	Joints/regions assessed	Total score	Hands	Feet	Year
Steinbrocker	Patient			0-4	X		1969
Kellgren	Patient			0-5	X		1963
Sievers	Patient			0-8	X		1965
Berens	Patient			0-5	X		1969
Scores based on the method developed by Sharp							
Sharp	Features	0-5 ERO, 0-4 JSN	54 ERO, 54 JSN	0-486	X		1971
Sharp (modified Sharp)	Features	0-5 ERO, 0-4 JSN	46 ERO, 48 JSN (42 JSN)	0-422 (-398)	X	X	2000
Genant (modified Sharp)	Features	0-3.5 (steps of 0.5) ERO, 0-4 JSN	28 ERO, 13 JSN	0-150	X	X	1983
Bluhm (modified Sharp)	Features	0-5 ERO; 0-4 JSN	34 ERO, 36 JSN	0-314	X		1983
Nance/Kaye (modified Sharp)	Features	0,2-4 ERO, 0,2-5 JSN, 0,2-4 MLG	22 ERO, 28 JSN, 30 MLG	0-348	X		1986
van der Heijde (modified Sharp)	Features	0-5 (10)* ERO, 0-4 JSN	32 ERO, 30 JSN	0-448	X	X	1989
Simple Erosion Narrowing Score (SENS)	Features	0-1 ERO, 0-1 JSN	22 ERO, 21 JSN	0-86		X	1999
Scores based on the method developed by Larsen							
Larsen	Joint	0-5	22 (-28) 0-110 (-140)		X	X	1974
Gofton (modified Larsen)	Joint	0-4 ERO	48 ERO	0-192	X		1982
Scott (modified Larsen)	Joint	0-5	22 (-28)	0-110 (-140)	X	X	1995
Rau (modified Larsen)	Features	0-5 ERO	38 ERO	0-190	X		1995
Kaarela/Kautiainen (modified Larsen)	Joint	0-5	20	0-100	X	X	1997

*Erosions of the feet are scored on the proximal and distal aspect of the joint, which results in a possible score per joint of 10.

ERO, erosions; JSN, joint space narrowing.

benchmark to assess structural effects induced by subsequent therapeutic regimens.

Other imaging modalities

Radiographic scoring appears to be a crude way to determine joint damage, and more sophisticated modalities are therefore of significant interest. Magnetic resonance imaging (MRI) and ultrasonography are two of these. By using contrast media (MRI) and power Doppler imaging, the vascularity of a lesion, such as in a synovial membrane, can easily be determined. Ultrasonography also allows one to assess cartilage thickness and to depict some erosions. MRI enables detection of erosions relatively early. Means of assessing cartilage damage by MRI are currently in development and primarily comprise measurement of joint space narrowing⁵⁵ because the currently routinely used MRI (1.5 and even 3 T) cannot easily depict cartilage anatomically. However, neither of these methods has been sufficiently validated as being meaningful to outcome. In addition, both have a number of limitations. Although ultrasonography is cost-effective, it is very time-consuming if one wants to depict all joints that are evaluated by hand and foot radiographs. Also, handling of the transducer is dependent on the investigator, and the angle may differ even within an individual patient with different states of joint swelling or stiffness. Moreover, some areas may escape visibility by ultrasonography. With MRI, on the other hand, aside from its cost, it is still difficult to depict changes in cartilage. Furthermore, the currently used MRI scoring system, the RA-MRI score (RAMRIS) and its modification,⁵⁶ looks at the wrist and metacarpophalangeal joints and thus does not account for the proximal interphalangeal joints, which are frequently involved in RA and included in the radiographic scores. Interestingly, in a recent trial, radiographic scores were found to be as sensitive to change as the RAMRIS.⁵⁷ Additionally, on a group level, radiographic changes can be depicted within 3 months of the start of treatment,⁵⁸ thus suggesting that radiographic assessment in RA is currently not inferior to other imaging modalities in its sensitivity to change or time until detectability of change, whereas other modalities are still more expensive, more time-consuming, or both. Most importantly, although radiographic changes have been associated with time-integrated disease activity on the one hand and disability on the other hand, these data still need to be provided and validated for ultrasonography and MRI.

For further reading on imaging, see Chapter 88.

OTHER INSTRUMENTS: FATIGUE, WORK PRODUCTIVITY, AND COMORBIDITY

It has already been mentioned that one of the many features of RA is fatigue. Although the mechanisms underlying fatigue are not clear but might involve direct or indirect consequences of the release of cytokines on the central nervous system or may be related to pain, depression, anemia, or other aspects of the disease, it is a fact that clinical improvement generally leads to improvement in fatigue. Various scales have been used, among them simple VAS or the more complex Functional Assessment of Chronic Illness Therapy (FACIT) fatigue scale,⁵⁹ which ranges from 0 to 52, with higher scores meaning less fatigue and an MCID of 4.

Another important outcome relates to work productivity. A variety of instruments have been developed and validated and are increasingly being used in clinical trials to address the impact of the disease and consequences of therapeutic interventions on ability to work. The data provide one of the bases for health economic analyses. Providing information on these instruments would go beyond the scope of this chapter, and the reader is referred to recent review articles.⁶⁰

Likewise, comorbid conditions not only influence disease outcome but also frequently limit the applicability of certain therapies. Several instruments are available.⁶¹ Although their value in RA has not yet been sufficiently validated, assessment of comorbidity may provide additional important insight in our understanding of RA, response to therapy, and the extent of loss of physical function and productivity with this disease. Finally, a very important aspect of caring for patients with chronic disease is prevention of drug toxicity. Clinical trials usually report on the more frequent adverse events within the short-term horizon of the respective studies, but observational studies and registries have been set up to identify rarer events and the long-term consequences of therapy. No uniform method of assessing toxicity is currently available, especially when feasibility is an issue, such as in clinical practice.

CONCLUSION

RA is a complex systemic disease. Outcomes assessment in RA is therefore also more complex than for other chronic diseases. The three main areas of

outcomes are disease activity, joint damage, and functional impairment. Each of these areas is represented by various domains, each of which again can be assessed with various instruments. This makes the field not easily transparent at first sight. Consistently, though, in the past until now, disease activity has been found to be reflected best by using a core set of measures that include joint counts, global scales, pain scores, and acute-phase response. Ideally, however, in clinical trials and clinical practice, these measures need to be combined into single summary measures (scores, indices)

so that clear targets for treatment can be defined. The benefit of treatment strategies targeted at specific outcomes has been elucidated only in the past few years and cannot be overemphasized. At the same time, the level of functional capacity and radiographic damage needs to be considered when outcomes are assessed or treatment decisions are made. All three areas—activity, function, and damage—are linked, with one influencing the other, and all three are determinants of the most important outcome, which is a patient's quality of life.

Management of rheumatoid arthritis: synovitis

■ LAURA GERALDINO-PARDILLA ■ JOAN M. BATHON

- Complete remission of rheumatoid arthritis (RA) disease activity should be the ultimate goal of treatment for all RA patients.
- Early, aggressive treatment of synovitis is desirable to have the greatest impact in preventing damage and disability.
- Patients with risk factors for poor prognosis warrant the most aggressive suppression of synovitis.
- Step-up combination approaches, beginning with rapidly titrated methotrexate, are the best studied and most commonly used strategies in clinical practice.
- First-line combinations of biologic and nonbiologic disease-modifying antirheumatic drugs may be warranted in patients with the poorest prognosis.
- Emerging targeted therapies hold great therapeutic promise and may alter current treatment paradigms in the future.
- The use of bridging and/or low-dose corticosteroids, nonsteroidal antiinflammatory drugs, and simple analgesics is often required for maximal management of symptoms.

INTRODUCTION

Rheumatoid arthritis (RA) is a systemic disease with both articular and extraarticular features and a primary pathologic process characterized by inflammation and hypertrophy of the synovial lining of diarthrodial joints, a process referred to as *synovitis* (see Chapter 20). If left untreated or inadequately suppressed, chronic synovitis will result in joint destruction and dysfunction. In general, only treatment strategies that successfully suppress synovitis are associated with improvements in articular pain, stiffness, and physical functioning as well as reduction of joint deformity, disability, and, possibly, mortality.

The currently available therapeutic agents used for the treatment of RA have been discussed in detail in previous chapters (Chapters 46 to 70). Drawing on the American College of Rheumatology (ACR) 2012 RA treatment guidelines and U.S. Food and Drug Administration (FDA) indications, this chapter outlines management strategies for RA taking into account individual characteristics of the patient, the disease, and the therapies that will influence outcomes and response to treatment. The important roles of physical and occupational therapy (Chapter 47), pain control (Chapter 50), joint surgery (Chapter 69), patient education (Chapter 46), complementary therapies (Chapter 48A), and a multidisciplinary approach to RA (Chapter 98) are reviewed in detail in other sections of this book.

HISTORICAL BACKGROUND

Finding safe and effective strategies to suppress synovitis in order to reduce or prevent disability and pain has always been the primary aim of the pharmacologic management of RA. However, only in the past several decades, with the evolution of molecular biology and a concomitant explosion in large-scale randomized clinical trials, have therapies with favorable benefit-risk profiles have been identified or confirmed.

The use of high doses of salicylates and glucocorticoids in the first half of the 20th century, although revolutionary, was accompanied by unacceptable degrees of toxicity. From the mid-20th century until the mid-1980s, a

slow, cautious approach to the treatment of RA, known as the *pyramid approach*, was most widely practiced. This consisted of a prolonged period of treatment with nonsteroidal antiinflammatory drugs (NSAIDs), with or without glucocorticoids, before adding a disease-modifying antirheumatic drug (DMARD). The prescription of one of a limited array of DMARDs available at the time (e.g., gold salts, penicillamine) was often delayed because of their limited efficacy, risk of major toxicities, and potential to lose their effectiveness over time. If the DMARD of choice was ineffective in controlling synovitis, it was discontinued in favor of an alternative DMARD. Not surprisingly, the pyramid approach inevitably resulted in some degree of joint destruction and disability in nearly all RA patients.

By the 1980s, the introduction and gradual acceptance of low-dose weekly methotrexate as a highly effective treatment for RA with relatively low toxicity prompted the abandonment of the pyramid approach in favor of much earlier DMARD use in RA patients. The use of nonbiologic DMARDs in combination and the recent introduction of biologic DMARDs have moved the notion of early, aggressive treatment of RA forward, so that complete remission of RA disease activity should be the ultimate goal of treatment for all RA patients.

WHAT IS AGGRESSIVE THERAPY?

More than half of RA patients develop erosions visible on plain radiographs within just 2 years of disease onset, and some data suggest that the rate of radiographic damage may be higher in the first years of disease.¹ Thus early and aggressive treatment is desirable to achieve the greatest impact in preventing damage and disability,² yet treatment initiated or ramped up at any phase of the disease will still be capable of decreasing inflammation and preventing additional damage.

The importance of “aggressive” management of RA is now generally accepted. A reasonable definition of aggressive management is a treatment strategy that is rapidly and maximally escalated to a level that suppresses synovitis without inducing an unacceptable burden of adverse effects. The ACR 2012 recommendations for the use of nonbiologic and biologic DMARDs in RA present evidence-based treatment algorithms for initiating or changing agents based on the duration of disease, level of disease activity, and features indicating poor prognosis (described later).³ Under these guidelines, in patients with early RA who have no risk factors for poor prognosis, early initiation and rapid dose escalation of nonbiologic DMARD monotherapy may be sufficient to control disease activity effectively. In contrast, in those with early RA who have moderate or high disease activity and poor prognostic features, the use of nonbiologic DMARD combination therapy or a tumor necrosis factor (TNF) inhibitor biologic with or without methotrexate is recommended. Thus the notion of aggressive management is somewhat fluid with regard to the choice of agent(s), the number of agents, and the rapidity of dose escalation of each of the agents, because these are dictated by the profile of the patient being treated. For each individual, the choice of treatment depends on an analysis of the benefit the patient is expected to gain from that treatment versus the potential risks associated with the treatment or combination of treatments. The ability early in disease to differentiate patients with a poor prognosis from those with a good prognosis allows therapeutic regimens to be individually tailored to produce the highest benefit-risk ratio for each patient.

PREDICTORS OF POOR OUTCOME

There is no single clinical, laboratory, or imaging parameter that is sufficiently sensitive to clearly identify patients who are at the highest risk of a

poor outcome (e.g., disability). However, prediction models based on combinations of factors have been developed⁴ in which radiographic progression of erosive disease serves as the surrogate for poor outcome because periarticular erosions can be assessed inexpensively over time, accumulate in proportion to burden of disease, and predict long-term disability.⁵

Several patient characteristics assessed early in disease have been associated consistently with the likelihood of developing erosive damage. The factors with the strongest predictive value include presence and titer of autoantibodies (e.g., rheumatoid factor [RF] and anti-cyclic citrullinated peptide [anti-CCP] antibodies); genetic factors (the presence of HLA-DRB1 “shared epitope” alleles, especially HLA-DRB1*0401 and HLA-DRB1*0404); radiographic factors (the presence of erosive disease on plain radiographs at presentation); inflammatory markers (e.g., elevated C-reactive protein [CRP] level and erythrocyte sedimentation rate [ESR]); and degree of functional disability (measured using the Health Assessment Questionnaire).^{6,7} All of these variables are easily and inexpensively assessed in the routine clinical setting. However, because the shared epitope status correlates closely with other clinical risk factors (e.g., anti-CCP antibodies) and thus adds minimal additional predictive value, it is not routinely assessed in clinical practice.⁴ The ACR 2012 treatment recommendations specifically define poor prognostic features as the presence of one or more of the following: functional limitations (measured by the Health Assessment Questionnaire or similar validated tools), extraarticular disease (e.g., rheumatoid nodules, RA vasculitis, Felty syndrome), the presence of RF or anti-CCP antibodies, and bony erosions by radiograph. It is important to keep in mind that, although the presence of these factors increases the risk of erosive disease, their absence does not guarantee a benign course.

Currently international efforts are underway to systematically evaluate imaging modalities with greater sensitivity for detecting erosions, such as ultrasonography and magnetic resonance imaging, for their potential role in enhancing detection, monitoring disease progression, and predicting future joint damage in patients with RA (see Chapters 41 and 42).

TREATMENT STRATEGIES

Rationale

No single clinical, laboratory, or radiographic parameter has been identified to date that can reliably predict a favorable response to a particular therapy. Furthermore, the paucity of head-to-head comparisons of different DMARDs does not allow, as yet, the rank ordering of individual DMARDs, or combinations of nonbiologic and/or biologic DMARDs, with regard to safety and efficacy. Nonetheless, a number of highly effective treatment strategies have been identified through clinical trials in RA that allow the clinician to organize the selection, order of use, and dosing of DMARDs for an individual patient. There are three general strategies for DMARD treatment of RA: sequential monotherapy, step-up combination therapy, and initial combination (induction) therapy.

Sequential monotherapy, a strategy in which an ineffective DMARD is replaced by an alternate DMARD, has largely been abandoned in favor of step-up and initial combination approaches. The last two approaches use combinations of nonbiologic DMARDs or a combination of a nonbiologic and a biologic DMARD. These approaches can be applied early or in established disease, although most commonly these strategies are discussed in reference to patients with early (DMARD-naïve) disease.

Criteria for assessing response to therapy have been developed for use in clinical trials and are discussed in detail in Chapter 96. Among these, the Disease Activity Score (DAS) and the modified DAS based on evaluation of 28 joints (DAS28), have been the most commonly used in clinical trials. However, because use of the DAS system requires complex calculations that limits their use in clinical practice, simpler scores have been developed and validated, including the Composite Disease Activity Index and the Simplified Disease Activity Index.³ Changes in disease activity scores with treatment are used to define outcomes as well as states of low disease activity and remission.

The step-up approach is currently the most widely practiced strategy in clinical practice for the management of RA⁸ and is the strategy used in the majority of clinical trials in RA to date. In this approach, a second agent (e.g., another nonbiologic DMARD or a TNF inhibitor) is added to the first DMARD (e.g., methotrexate) if a response to the first DMARD is inadequate. In most published step-up combination approaches, methotrexate serves as the “anchor” DMARD. The advantage of the step-up strategy is that it permits graded escalation of therapy up to the desired level of control of synovitis without exposing the patient to more DMARDs than are necessary. The disadvantage is that a lag time, which varies depending on how many

steps are required, must elapse before disease control is attained. During this time, irreversible articular damage may occur. For this reason, the model step-up strategy outlined in the 2012 ACR guidelines for the management of RA³ advocates frequent evaluation and rapid escalation of therapy in the face of incomplete response.

In contrast, in induction therapy (modeled after cancer chemotherapy strategies) the patient is immediately given a combination of DMARDs. Once maximal or acceptable control of synovitis is achieved, the combination may be continued indefinitely or stepped down to a single DMARD for maintenance. The theoretical advantage of induction therapy is more rapid control of synovitis and thus less accumulation of joint damage compared with the sequential monotherapy and step-up approaches. The disadvantages of the induction approach are potential overtreatment and exposure to unnecessary toxicities in patients in whom disease may have been adequately controlled by a single DMARD; in addition, there can be difficulty in attributing an adverse event to a specific drug.

A landmark study of induction with step-down was the Dutch Combinatietherapie Bij Rheumatoïde Artritis (COBRA) trial⁹ in which patients with early RA were randomly assigned to initial treatment with sulfasalazine alone or sulfasalazine plus methotrexate plus high-dose prednisolone, with taper from high-dose to low-dose prednisolone by week 6 and taper to sulfasalazine monotherapy by 6 months. Radiographic outcomes in the induction/step-down group were superior to the those in the monotherapy group at the end of 6 months, a difference that persisted through 5 years of follow-up even though the randomized treatment phase had long since ended. Similar clinical and radiologic results were reported in the Finnish Rheumatoid Arthritis Combination Therapy Study (FIN-RACo)¹⁰ in which treatment with combination DMARDs with step-down was compared with DMARD monotherapy over 5 years of follow-up.

The results from these studies and others² have led to the speculation that a window of opportunity exists early in the disease during which aggressive treatment may serve to permanently slow, or even halt, disease activity.¹¹

A head-to-head comparison of induction versus step-up versus sequential monotherapy strategies was performed in the Behandel-Strategieën in Reumatoïde Artritis (Treatment Strategies in Rheumatoid Arthritis, or BeSt) trial.¹² Data from this study indicate that two different induction regimens—(1) the COBRA induction/step-down regimen of nonbiologic DMARDs, and (2) a combination of infliximab plus methotrexate—were superior to sequential monotherapy and step-up combinations in slowing radiographic progression over 12 months, but all four regimens attained comparable clinical improvements by month 12. More recently the Treatment of Early Aggressive RA (TEAR) trial¹³ assessed the DAS28-ESR values from week 48 to week 102 in patients with early RA immediately treated with a combination of methotrexate plus etanercept or a combination of methotrexate plus sulfasalazine plus hydroxychloroquine, compared with step-up from methotrexate monotherapy at week 24 to one of the two induction regimens if the DAS28-ESR was 3.2 or higher. Immediate induction regimens were superior to methotrexate monotherapy at week 102, but there was no difference in the mean DAS28-ESR during weeks 48 to 102 for the methotrexate plus etanercept and triple-therapy groups regardless of whether they had received immediate induction or step-up from methotrexate monotherapy. However, radiographic progression was modestly lower in the methotrexate plus etanercept group than in the triple-therapy group.¹³ Moreover, data from the Swefot trial¹⁴ demonstrated that in patients with early RA refractory to methotrexate monotherapy after 3 to 4 months of treatment, those given methotrexate plus infliximab showed better clinical response than patients given methotrexate plus sulfasalazine plus hydroxychloroquine at 12 months but not at 24 months, although better radiographic outcome at 24 months was seen in the methotrexate plus infliximab arm.

Finally, “individualized targeted tight control” is a variant on each of these approaches in which the rapid attainment of low disease activity or remission is set as the goal of therapy. The prototype of this approach was the regimen used in the Tight Control for Rheumatoid Arthritis (TICORA) trial¹⁵ in which treatment in an “aggressively managed” group was escalated at each study visit if the DAS score was higher than 2.4. In contrast, in the “routine care” group, the DAS score was not a part of the clinical decision-making, and these patients received therapy at the discretion of the treating rheumatologist. At the end of 18 months of treatment, patients treated intensively showed superior clinical responses and fewer radiographic erosions than those in the routine care group.

In summary, the evidence to date suggests that aggressive treatment to rapidly achieve a low level of disease activity, which often necessitates use of a combination of agents, is more effective than conservative approaches that involve sequential low-dose monotherapy. Given the expense of combination therapy, especially treatment with the biologic agents, and the

TABLE 97.1

Disease-modifying antirheumatic drugs (DMARDs) and biologic agents

DMARDs	Mechanism of action	Biologics	Mechanism of action
Methotrexate	Inhibition of purine biosynthesis and cytokine expression; induction of monocyte apoptosis	Etanercept	Soluble 75-kDa TNF receptor; inhibits TNF- α .
Sulfasalazine	Inhibition of cytokine expression and neutrophil migration	Infliximab	Chimeric anti-TNF- α antibody; inhibits TNF- α .
Leflunomide	Inhibition of pyrimidine biosynthesis, cytokine expression, and neutrophil migration	Adalimumab	Human anti-TNF- α antibody; inhibits TNF- α .
Hydroxychloroquine	Unknown	Golimumab	
Minocycline	Inhibition of metalloproteinases—exact mechanism unknown	Certolizumab	Pegylated human anti-TNF- α antibody; inhibits TNF- α .
		Abatacept (CTLA-4-immunoglobulin)	Inhibits T-cell costimulation.
		Rituximab	Anti-CD20 monoclonal antibody; depletes B cells.
		Tocilizumab	Humanized anti-IL-6 receptor antibody; inhibits IL-6.
		Anakinra	Recombinant IL-1 receptor antagonist; inhibits IL-1.

IL, interleukin; TNF, tumor necrosis factor.

current environment of cost containment, the step-up approach rather than the induction (combination) approach remains the most common in clinical practice.⁸ However, the ACR 2012 treatment guidelines³ do sanction the use of initial combination regimens of DMARDs with or without a TNF inhibitor for patients with high disease activity and features indicating poor prognosis.

The remainder of this chapter focuses on specific nonbiologic and biologic DMARDs (Table 97.1), as well as DMARD combinations, with the step-up approach in mind.

CHOICE OF INITIAL THERAPY

In most cases, except when there are specific contraindications or high disease activity with poor prognostic features, a nonbiologic DMARD is recommended as the initial therapy in a DMARD-naïve patient with early disease.³ Although biologic agents are also effective in early disease, their significantly higher cost generally limits their use as first-line agents.

In DMARD-naïve patients with early RA (disease duration of less than 6 months), the ACR 2012 panel recommends starting DMARD monotherapy for disease of all degrees of severity in the absence of poor prognostic factors. In the presence of poor prognostic features and moderate or high disease activity, double- or triple-DMARD combination therapy or an anti-TNF agent (with or without methotrexate) is recommended.

In DMARD-naïve patients with longer disease duration (6 months or more), low disease activity, and no features of poor prognosis, DMARD monotherapy is recommended.³ For those with poor prognostic factors and/or moderate to high disease activity, methotrexate monotherapy or DMARD double or triple therapy is recommended as initial treatment.

Methotrexate monotherapy as the standard first-line DMARD

Methotrexate is generally accepted as the first-line DMARD of choice due to its marked efficacy, safety, tolerability, and sustainable effect (see Chapter 56). Consequently, most clinical trials have tested the safety and efficacy of new drugs in combination with methotrexate.

Aggressive dose escalation of methotrexate has gained relatively widespread acceptance in recent years on the basis of its favorable safety profile. A paradigm for rapid escalation was provided by the Early RA (ERA) study¹⁶ in which methotrexate treatment was initiated at a dosage of 10 mg/wk and escalated by 5 mg every 4 weeks until a weekly dose of 20 to 25 mg was achieved, provided that adverse effects did not necessitate stopping at a lower dosage. In practice, many patients tolerate an initial dose of 15 mg/wk. In this study and others in patients with either early¹⁶⁻¹⁸ or advanced¹⁹ RA, aggressively titrated methotrexate monotherapy was comparable to TNF inhibitor monotherapy in reducing clinical signs and symptoms of RA, although cumulative radiographic joint damage over several years was slightly higher in the methotrexate group at 1 to 2 years of follow-up.

Because of the slow onset of action of methotrexate, an interval of 4 to 6 weeks is generally required to determine whether a patient has responded to a dose increase. Thus when the dosing strategy described earlier is used,

an interval of 3 months is recommended to evaluate the initial response to methotrexate monotherapy. For patients who have had an inadequate response to 20 to 25 mg/wk of oral methotrexate, substitution of an equivalent dose of subcutaneous or intramuscular methotrexate may enhance efficacy. However, given the availability of an array of other DMARDs on the market, the addition of a second DMARD is the preferred next step in most patients showing no response to, or intolerant of, oral methotrexate.

Although the majority of patients tolerate rapid escalation of methotrexate, dose-limiting adverse effects related to drug-induced folate deficiency, such as hepatic transaminitis, stomatitis, nausea, cytopenias, and hair loss (see Chapter 56), may present barriers to continuing or escalating the drug. Methotrexate-induced folate deficiency has also been implicated as a contributor to the enhanced risk of cardiovascular disease in RA patients. Consequently, supplementation with folate (in the form of folic or folinic acid) is recommended for all methotrexate-treated patients because this appears to reduce adverse effects with minimal compromise of overall efficacy.²⁰ Although methotrexate is generally appropriate for most patients, absolute contraindications to it include active liver disease (including chronic hepatitis B and C), alcohol abuse, pregnancy, and breastfeeding. Alternative DMARD choices for these patients are discussed next.

First-line monotherapy with other nonbiologic DMARDs

Given the limited evidence for the use of nonbiologic DMARDs other than methotrexate in early RA, these agents are generally reserved for patients who have a contraindication to methotrexate use. Of this group of DMARDs, sulfasalazine, leflunomide, and hydroxychloroquine are the most commonly used. The first two of these drugs were shown in placebo-controlled randomized clinical trials^{21,22} to be relatively comparable in their abilities to reduce articular signs and symptoms of RA, improve physical function, and retard radiographic progression (Chapters 55 to 57).

Leflunomide, a pyrimidine synthesis inhibitor (see Chapter 57), has been shown in head-to-head trials in established RA to have efficacy equivalent to that of methotrexate or sulfasalazine in suppressing synovitis and inhibiting radiographic progression,^{21,22} although it could be argued that both methotrexate and sulfasalazine were underdosed in these trials. The usual dosage of leflunomide is 20 mg/day, but it can be reduced to 10 mg/day in cases of toxicity. Its contraindications for use (alcoholism, pregnancy, active liver disease, and renal impairment) and adverse effect profile (requiring routine monitoring of transaminase levels) are similar to those of methotrexate.

The efficacy of sulfasalazine (see Chapter 55) in the treatment of RA was first recognized in the 1940s, although its mechanism of action in RA has never been clearly elucidated. Head-to-head studies have shown it to be generally equivalent in efficacy to methotrexate and leflunomide,^{23,24} although methotrexate was underdosed in these studies relative to current clinical practice. The usual dosage of sulfasalazine for the treatment of RA is 1 to 3 g/day in divided doses. Sulfasalazine is contraindicated in patients with sulfa allergy or glucose-6-phosphate dehydrogenase deficiency. Potential advantages of sulfasalazine over methotrexate include its reduced cost, relative safety during pregnancy, and low incidence of hepatotoxicity and

bone marrow toxicity. Sulfasalazine is an important option for RA patients with chronic hepatitis C or other liver conditions. Comparative disadvantages include a higher rate of early discontinuation due to intolerance (usually gastrointestinal adverse effects) and the potential for lower patient compliance because of the need for twice-daily dosing.

Neither leflunomide nor sulfasalazine has been studied in combination with other nonbiologic and biologic DMARDs as rigorously as has methotrexate. For these and the other reasons cited earlier, methotrexate remains the most commonly used first-line DMARD for RA, although both leflunomide and sulfasalazine are reasonable alternatives.

Hydroxychloroquine (see Chapter 55) has a long track record of use in the treatment of RA. Its low toxicity, ease of administration (orally once or twice daily), low cost (comparable with that of methotrexate and sulfasalazine), and apparent safety in pregnancy make it an attractive agent for use in RA. However, head-to-head studies comparing it with the other conventional DMARDs² confirm that hydroxychloroquine is a comparatively less potent DMARD. Furthermore, limited data on its ability to slow radiographic progression largely relegate this agent to treatment of very mild disease without poor prognostic factors or use in combination with other DMARDs. The usual dosage is 200 to 400 mg/day with monitoring for retinal toxicity advised at baseline and annually after 5 years.

Other agents once used to treat RA, including oral and injectable gold, D-penicillamine, minocycline, cyclosporine, tacrolimus, cyclophosphamide, and azathioprine (see Chapters 55 and 58), are now rarely used due to a poor evidence base for efficacy in RA and/or high toxicity relative to currently available agents.

First-line monotherapy with biologic DMARDs

Five TNF inhibitors (etanercept, infliximab, adalimumab, certolizumab, and golimumab) are U.S. FDA approved for the treatment of RA (see Chapter 63). Each has been demonstrated to be efficacious as monotherapy for the treatment of RA, although infliximab is recommended only in conjunction with methotrexate (to suppress antichimeric antibodies). Compared with aggressively dosed methotrexate, monotherapy with etanercept, adalimumab, or golimumab failed to show superiority in reducing clinical signs and symptoms of disease, although each did exhibit modest superiority in reducing radiographic progression.^{16,18,19,25,26} Nonetheless, this modest advantage is arguably offset by the high costs of these agents, so that methotrexate remains the preferred first-line DMARD. There are patients, however, in whom first-line monotherapy with TNF inhibitors other than infliximab is preferred, such as those with contraindications to nonbiologic DMARDs. Evolving clinical experience suggests that TNF inhibitors may be relatively safe during conception and possibly even during pregnancy,²⁷ although more study is required. Insofar as the most common use of TNF inhibitors is in combination with methotrexate, these drugs are addressed in greater detail in the discussion of step-up therapy.

Step-up therapy

Approximately 50% of patients have an inadequate response to monotherapy with an aggressively dosed DMARD.^{16,17,21,22,24} If after 3 months of monotherapy with a nonbiologic DMARD a patient's condition deteriorates from low to moderate or high disease activity, then the addition of a second nonbiologic DMARD is recommended at this point. As always, the addition of any new DMARD poses additional risks that must be weighed against the potential benefit of additional treatment. If the disease activity remains moderate or high after 3 months of methotrexate monotherapy or methotrexate in combination with another nonbiologic DMARD, it is recommended to add or switch to another nonmethotrexate DMARD, or to add or switch to one of the following biologics: a TNF inhibitor, abatacept, or rituximab.

If moderate to high disease activity still persists after 3 months of intensified DMARD combination therapy or after either switching to a second DMARD or adding one, then either adding or switching to an alternate TNF inhibitor or non-TNF-inhibitor biologic is recommended. If a TNF inhibitor is discontinued due to a serious adverse event and the patient has persistent high disease activity, switching to a non-TNF-inhibitor biologic agent is recommended. If the TNF inhibitor is discontinued due to a nonserious adverse event and the patient has persistent moderate to high disease activity, then switching to another TNF inhibitor is appropriate.³

Nonbiologic DMARD combinations

As noted previously, combinations of nonbiologic DMARDs administered using the induction approach have shown substantial superiority to

monotherapy for the treatment of RA. This is also demonstrated in clinical trials using the step-up approach. For example, the combination of sulfasalazine plus hydroxychloroquine plus methotrexate was superior to methotrexate alone, to sulfasalazine alone, and to the dual combinations²⁸ for reducing signs and symptoms of disease, although radiographic assessments were not performed in these studies. This strategy, termed *triple therapy*, is generally well tolerated and is relatively low in cost. Disadvantages include a dosing scheme that may present barriers to adherence in some patients and the potential for a negative effect of sulfasalazine plus methotrexate due to sulfasalazine's inhibition of cellular uptake of methotrexate by the reduced folate carrier.

The addition of leflunomide to methotrexate in patients showing an inadequate response to methotrexate was also associated with enhanced clinical improvement compared with methotrexate alone, but no radiographic endpoints were assessed. Drug-related toxicities associated with the combination are relatively low; however, careful monitoring of hepatic function is advised in patients receiving this combination. Suggested ways to minimize toxicity are the initiation of leflunomide at the lower (10 mg/day) dosage and reduction of the dosage of methotrexate. Head-to-head comparisons pitting methotrexate plus leflunomide against regimens containing a TNF inhibitor have not been performed. For these reasons, nonbiologic DMARD combinations are often selected in patients with contraindications to TNF inhibitors (e.g., patients with recurrent serious infections) or those with an aversion to self-injection or infusion.

Biologic agents

Tumor necrosis factor inhibitors

The combination of a TNF inhibitor plus methotrexate has been demonstrated to be superior to monotherapy with methotrexate in reducing signs, symptoms, and radiographic progression of disease in patients with early or advanced RA; this superiority was shown for etanercept in the TEMPO trial,¹⁹ for infliximab in the ASPIRE and ATTRACT trials,^{29,30} for adalimumab in the PREMIER and ARMADA trials,^{18,31} for certolizumab in the RAPID 1 and 2 trials,^{32,33} and for golimumab in the GO-FORWARD, GO-FORTH, and GO-FURTHER trials.^{26,34,35} The ability of TNF inhibitors to produce robust, rapid, and sustainable clinical responses in many patients has overshadowed, but not eclipsed, concerns about short- and long-term toxicities. These toxicities include enhanced risk of serious and opportunistic infections, induction of autoantibodies, and risk of inducing or exacerbating symptoms of congestive heart failure and of demyelinating diseases (see Chapter 63). Fortunately, the incidence of these potential adverse effects is low. The increasing prescription of TNF inhibitors over the years since FDA approval has demonstrated that self-injection and intravenous infusion are acceptable routes of administration for the treatment of patients with RA. In patients at high risk of joint damage, the high cost of TNF inhibitors is expected to be balanced or offset in the long term by a reduction in joint surgeries, disability, and unemployment. Thus their use as add-on therapy on a background of methotrexate in patients with moderate to high disease activity is now relatively commonplace.

No evidence suggests that one TNF inhibitor is superior to another. Furthermore, potential adverse effects are generally comparable among the five, although infliximab treatment has been associated with a higher incidence of opportunistic infection.³⁶ Therefore the selection of a TNF inhibitor is often based on patient preference. Etanercept, adalimumab, certolizumab, and golimumab are self-administered via subcutaneous injection (50 mg weekly or 25 mg twice per week for etanercept; 40 mg every 1 to 2 weeks for adalimumab; 400 mg at 0, 2 and 4 weeks then 200 mg every 2 weeks or 400 mg every 4 weeks for certolizumab; and 50 mg every 4 weeks for golimumab). Infliximab is administered as an intravenous infusion every 8 weeks (after an initial loading regimen). The standard dose of infliximab, 3 mg/kg, can be titrated up to 10 mg/kg if needed and/or the dosing interval can be decreased (to every 6 or 4 weeks). It is recommended that infliximab be administered concurrently with methotrexate (at least 7.5 mg/wk) to prevent the development of neutralizing antibodies. Data suggest that the combination of a TNF inhibitor with DMARDs other than methotrexate (e.g., leflunomide and/or sulfasalazine) is safe and perhaps efficacious as well.³⁷⁻³⁹ Formal drug interaction studies, however, have not been done with these drugs and the anti-TNF therapies. Combining TNF inhibitors or combinations of TNF inhibitors with other biologic agents is not recommended³ because of the risk of enhanced infection and other toxicities.⁴⁰

In general, the onset of action of TNF inhibitors is more rapid than that of nonbiologic DMARDs, and many patients show a clinical response after only 8 to 12 weeks of therapy. However, some patients may be slower to respond, and, as with methotrexate, approximately 50% of patients fail to

show a robust response to anti-TNF therapy at all.^{16,17,30,31} The factors responsible for this variability are not known.

T-cell costimulatory modulators

The T-cell costimulatory modulator abatacept (soluble CTLA-4-immunoglobulin) (see Chapter 59), is FDA approved as monotherapy or in combination with nonbiologic DMARDs for moderate to severe RA given its efficacy in reducing clinical signs and symptoms as well as radiographic progression in methotrexate-naïve patients⁴¹ and those showing inadequate response to nonbiologic DMARDs and/or TNF inhibitors.⁴²⁻⁴³ In a randomized trial performing a head-to-head comparison of the efficacy of abatacept and a TNF inhibitor (infliximab) in patients who had active RA despite treatment with methotrexate, clinical response outcomes were similar over 1 year,⁴⁶ although infliximab was initiated at the minimum (3 mg/kg) dose with no provision for escalation.

Overall, the safety profile of abatacept based on clinical trial data is modestly superior to that of TNF inhibitors. Infusion reactions were lower in abatacept-treated patients than in infliximab-treated patients,⁴⁶ and no cases of tuberculosis or other opportunistic infections were associated with abatacept use in the 5-year safety data from the ATTAIN trial.⁴⁷ In particular, potential signals of lung cancer and exacerbations of chronic obstructive pulmonary disease noted in a large safety trial (ASSURE)⁴⁴ have not been replicated in subsequent studies, but further monitoring is warranted.

Abatacept is the only biologic agent available in both subcutaneous and intravenous formulations. It is administered according to weight and a loading regimen is recommended. Thereafter, infusions every 4 weeks or subcutaneous injections every week are administered. Because the onset of clinical effect can be delayed, a recent consensus statement recommends continuing abatacept for at least 16 weeks before evaluating efficacy.

Abatacept should not be combined with TNF inhibitors because the combination has been associated with higher infection rates in the absence of improved efficacy.

B-cell depleter

Rituximab is a chimeric monoclonal antibody directed against CD20 (see Chapter 60). It has been approved by the FDA for use in combination with methotrexate for the treatment of moderate to severe RA in adults who have shown an inadequate response to one or more TNF inhibitors because of its efficacy in reducing synovitis and in slowing radiographic progression in this population.⁴⁸⁻⁵⁰ Rituximab has also been tested in combination with TNF inhibitors plus methotrexate but did not offer any further advantage in efficacy compared with combined TNF inhibitor/methotrexate therapy and increased the number of severe adverse events.⁴⁰ Evidence suggests enhanced efficacy in RA populations who are seropositive for RF; however, rituximab has been used with success in seronegative patients as well.⁴⁸ These and other studies showing lack of correlation between peripheral depletion of B cells, or change in titers of RF and/or anti-CCP titers, with clinical response call into question the exact mechanism of action of rituximab in RA.

The safety profile for the first treatment course of rituximab is generally favorable, with few serious infections and no opportunistic infections noted in clinical trials. Infusion reactions are more frequent with rituximab than with the other infused biologic agents, which led to the recommendation for pretreatment with corticosteroids. Infusion reactions tend to diminish with repeated infusions. Reductions in immunoglobulin levels have been noted over repeated courses of treatment. These decreases have not been associated with an increased risk of infection to date, although in the 1% of patients with sustained decreases in immunoglobulin G, a non-statistically significant trend toward an increased risk of infection was noted. Furthermore, low pretreatment levels of immunoglobulin G have been identified as a risk factor for severe infections.⁵¹ Sporadic cases of progressive multifocal leukoencephalopathy have been reported in patients receiving rituximab for non-Hodgkin lymphoma, systemic lupus erythematosus, and RA,⁵² although most of these patients were also receiving immunosuppressive agents.

Rituximab is administered as two doses of 1000 mg separated by 2 weeks (hereafter referred to as a *treatment course*), although one study showed nearly equivalent efficacy with two 500-mg infusions. The duration of effect is variable but is typically longer than 6 months.⁵³ Durable responses of 18 months and longer have been reported after one course of treatment.⁵⁴ In some cases, subsequent treatment courses resulted in longer duration of response. Although levels of peripheral B cells are rapidly diminished after treatment in most cases, reemergence of B cells does not predict loss of response and continued depletion does not guarantee maintenance of response. In the SUNRISE⁵⁵ trial, those who were treated with a second rituximab course at 6 months had improved and sustained efficacy at 1 year compared with those treated with only one course, and the safety profiles

for the two treatment conditions were similar. Although initially it was thought to be futile to administer a second course of treatment to patients unresponsive to the first course, a more recent study showed that administration of a second treatment course was associated with a significant improvement in the DAS28 score in 72% of patients.⁵⁶

Some concern has been raised about the safety of initiating another biologic therapy in patients who have shown an inadequate clinical response to rituximab but still have peripheral B cell depletion. However, preliminary evidence suggests that starting a TNF inhibitor in this setting may be safe.⁵⁷

Interleukin-6 inhibitor

Tocilizumab is a humanized anti-interleukin-6 (IL-6) receptor monoclonal antibody (see Chapter 62) approved for treatment of systemic juvenile idiopathic arthritis and adult RA in patients in whom treatment with at least one TNF inhibitor has failed. Several randomized controlled trials⁵⁸ and additional open-label phase 3b/4 trials have shown its short- and long-term efficacy in improving RA signs and symptoms and slowing radiographic progression in treatment-naïve patients and in patients showing inadequate response to nonbiologic and biologic (TNF inhibitor) DMARDs, both as monotherapy and in combination with methotrexate. Clinical response and decrease in C-reactive protein levels have been noted as early as 4 and 2 weeks, respectively, and improvement in hemoglobin levels is seen in the majority of those who meet response criteria.

The recommended starting dose is 4 mg/kg intravenously every 4 weeks with the option to increase to 8 mg/kg if needed for clinical response.

Overall, the safety profile of tocilizumab based on clinical trials is similar to that of the TNF inhibitors. Increased risk of infection (including tuberculosis and other opportunistic infections), rash, and abnormalities in laboratory values (e.g., neutropenia, elevations in liver enzyme and lipid levels) have been noted. Perforations of the gastrointestinal tract were also seen in a small number of patients treated with tocilizumab, especially those with a history of diverticular disease.

Although no head-to-head trials have been performed comparing tocilizumab with other DMARDs, tocilizumab appears to have efficacy comparable to that seen with TNF inhibitors in both clinical and radiographic outcomes. It is currently unknown which subset of patients would benefit most from this biologic agent, and at this time tocilizumab is usually administered as third-line therapy in patients in whom methotrexate and TNF inhibitor treatment has failed.

Interleukin-1 inhibitor

Anakinra (recombinant soluble IL-1 receptor antagonist), the only FDA-approved IL-1 inhibitor for the treatment of RA (see Chapter 61), is administered as a once-daily subcutaneous injection. It has been shown, both as monotherapy and in combination with methotrexate, to be superior to placebo in reducing signs, symptoms, and radiographic progression in patients with advanced RA. Although it has not been compared head to head with any of the TNF inhibitors, its efficacy in clinical trials is substantially lower than that of the TNF inhibitors. This, coupled with the inconvenient dosing schedule, has resulted in its diminished use in clinical practice and its exclusion from the ACR 2012 treatment recommendations.³

Glucocorticoids

Glucocorticoids (see Chapter 54) are potent antiinflammatory drugs that constitute important adjunctive therapy for RA but should never suffice as monotherapy for any prolonged period of time due to their substantial adverse event profile. In general, glucocorticoids should be prescribed at as low a dosage and for as short a time as possible. They can be administered orally or by intraarticular injection, intravenous infusion, or intramuscular injection. Glucocorticoids are particularly useful at the onset of disease because they produce a rapid and substantial reduction in pain and synovitis,⁹ and thus decrease patient discomfort while the slower-acting DMARD(s) takes effect. This bridging strategy, in which glucocorticoids are tapered and discontinued as the DMARD takes full effect, can also be applied during disease flares. In view of the adverse effects associated with long-term glucocorticoid administration (see Chapter 54), the associated benefit must always be weighed against the risk of toxicity.

Nonsteroidal antiinflammatory drugs

Concomitant prescription of an NSAID along with DMARDs intermittently or continuously throughout the course of RA is not uncommon. Many NSAIDs are available commercially and are discussed in detail in Chapter 53. Along with well-recognized gastrointestinal adverse effects, concerns of an increased risk of cardiovascular events have drawn into question the use

of this class of drugs for long-term treatment of RA and other inflammatory conditions.

MAINTENANCE OF THE TREATMENT RESPONSE

RA is a chronic disease that rarely remits spontaneously. Consequently, DMARD treatment must be continued indefinitely because its discontinuation generally leads to reemergence of signs and symptoms of disease within weeks to months. Patients who have been treated according to an induction regimen may tolerate a simplification of their treatment regimen to a single DMARD. Many patients experience a flare in disease activity over the course of their illness that necessitates an adjustment in treatment, usually in the form of increased dose or number of DMARDs.

FUTURE

A subset of RA patients do not respond adequately to aggressive therapy, and to date, no cure for RA is available. Fortunately, a number of new drugs with novel mechanisms of action and/or more convenient routes of administration (see Chapters 63 to 66) may provide alternatives for these patients. The most promising of these appear to be the small-molecule inhibitors of tyrosine kinases (i.e., syk and jak). In phase 2 studies, the syk inhibitor fostamatinib was shown to be efficacious in patients who showed inadequate response to methotrexate but not in those who showed inadequate response to biologic agents. In contrast, in two phase 3 randomized controlled trials the JAK-3/2 inhibitor tofacitinib showed clinical efficacy in patients with inadequate response to nonbiologic DMARDs, both as monotherapy and in combination with methotrexate, at 3 and 6 months, respectively.^{59,60} The dosages studied were 5 mg or 10 mg taken orally twice a day. Throughout the studies, the most frequent adverse events were infections, elevation in lipid levels, and cytopenias (mainly neutropenia and anemia). No data are available yet on the ability of either fostamatinib or tofacitinib to slow radiographic progression of disease.

In the coming years, additional research will establish where these agents fit in the evolving treatment algorithms for RA.

OTHER CONSIDERATIONS

Screening for latent tuberculosis is recommended for all RA patients being considered for therapy with biologic DMARDs. For patients with latent tuberculosis, antitubercular treatment should be initiated before biologic DMARD therapy is begun. Patients with risk factors for tuberculosis should continue to undergo annual screening while receiving biologic therapy. Regarding vaccinations, administration of killed vaccines (pneumococcus, influenza, hepatitis B), recombinant vaccines (human papillomavirus), and live attenuated vaccines (herpes zoster) is recommended before nonbiologic or biologic DMARDs are started. For nonvaccinated patients who are already receiving nonbiologic DMARDs, administration of all the aforementioned vaccines still is recommended. For nonvaccinated patients who are already receiving a biologic DMARD, live vaccines (e.g., herpes zoster) should be avoided, whereas the killed and recombinant vaccines may be administered.

BARRIERS TO AGGRESSIVE MANAGEMENT

The ability to escalate therapy to the desired level in an individual RA patient may be limited by the presence of one or more comorbid illnesses and/or patient behaviors. Comorbidities such as recurrent or chronic infections, chronic liver disease, malignancy, and moderate to severe congestive heart failure are relative contraindications to the use of some biologics or DMARDs as discussed earlier and in other chapters.

CONCLUSION

The treatment of RA has changed dramatically in the past decades. The initiation of treatment very early in disease, the use of combinations of DMARDs, and the emergence of the biologic agents have made it possible to achieve control of synovitis and improvement in quality of life in the majority of RA patients. Complete remission or low disease activity should be the goal of treatment in all RA patients. Indeed, emerging clinical and epidemiologic data suggest that excellent long-term control of synovitis will result in significant reductions in rates of unemployment, joint surgeries, disability, and mortality in RA patients.

Multidisciplinary approach to rheumatoid arthritis

■ INGVLID KJEKEN ■ HANNE DAGFINRUD ■ TURID HEIBERG ■ TORE K. KVIEN

- Patient education may improve pain, functional ability, depression, coping, and self-efficacy and should be a cornerstone in the multidisciplinary care of persons with rheumatoid arthritis (RA).
- Cognitive-behavioral therapy and mindfulness-based group intervention programs may improve fatigue and psychological distress.
- Nursing care provides continuity and the opportunity for shared decision making and focuses on the patient's coping strategies.
- Persons with RA have increased risk of cardiovascular diseases and osteoporosis. Health professionals should therefore promote physical activity and guide patients in achieving and maintaining a healthy lifestyle.
- Dynamic exercises are safe and beneficial for patients with RA, but patients with extensive joint damage or joint prostheses should be careful with high-intensity weight-bearing exercises.
- Physical modalities are a possible adjunctive method with uncertain benefits but no harmful effects.
- Orthopedic shoes, insoles, wrist orthoses, and splints correcting for foot or hand deformities, as well as assistive devices, may decrease pain and improve function.
- Persons with RA should follow a healthy diet, avoid certain foods if they have allergies or intolerance, and consult a nutritionist if they want to try any special diet.
- Persons at risk of being work disabled should have rapid access to vocational rehabilitation because prevention of work disability is probably more effective than correction of work disability after work loss.
- Team care such as comprehensive inpatient and day patient programs is more effective than regular outpatient care to control disease activity and improve functional ability.
- Transdisciplinary models, in which clinicians take on extended roles, may in many cases be at least as effective as and more cost effective than extensive team care.

INTRODUCTION

Over the past decades, new medical and surgical treatments have improved prognosis and quality of life for people with RA. Still, most patients experience periods with pain, fatigue, and loss of function and benefit from therapeutic interventions implemented by a variety of health professionals. The expectations for level of functioning and participation in society have also been raised along with these new opportunities for improvement.

A consumer-centered approach is now widely applied in disease management. Individual goals and treatment plans are jointly set by the patient and the rest of the team. The roles and areas of expertise of the potential team members¹ are described in Table 98.1. Even if each profession has different areas of expertise, a common goal is always to reduce and control disease activity, to maintain or improve function and work ability, and to enhance coping strategies and the quality of life of the patient and his or her family. How a team of health professionals work together depends, to a large degree, on the problems of the patient, the treatment setting, and the treatment goals. Traditionally, two models of care have been distinguished: a multidisciplinary approach, in which different team members cooperate on a regular basis while staying within their professional boundaries, and an

interdisciplinary team model, in which the members analyze, synthesize, and harmonize links between disciplines to establish a shared basis of knowledge and common goals in the treatment or rehabilitation of the patient.² Although patients with an aggressive disease, multiple problems, and/or a complex life situation may profit from application of the latter model, the multidisciplinary team model may be appropriate for patients with a stable disease and life situation. Also, some patients may prefer to interact with one or a few health professionals rather than an extensive team, and the involvement of fewer persons is likely to assist communication and partnership with the patient.¹

Lately, a third, so-called *transdisciplinary model* has emerged. In this approach, members transcend their traditional boundaries and take on extended roles to be able to meet a patient's need for more rapid access to care, to provide more time and continuity in care, or to provide a more optimal treatment when funding or human resources are limited. Examples of such models are care by clinical nurse specialists who conduct examinations and treatment monitoring usually performed by a rheumatologist and the primary therapist model, in which specially trained physical or occupational therapists function as multiskilled health professionals working in consultation with or with referral to peers or other services when necessary.²

Published recommendations for disease management often divide the recommendations into pharmacologic and nonpharmacologic interventions.³ Health professionals primarily work with nonpharmacologic interventions. This chapter reports the evidence for such interventions and discusses different care models.

NONPHARMACOLOGIC INTERVENTIONS

Successful multidisciplinary care depends on the availability of skilled health professionals as well as timely and coordinated delivery of the relevant interventions.

Patient education

The primary target of patient education is the disease consequences: symptoms and disability. Promoting independence, feelings of being in control, and confidence are also major aims. The implication is that cognitive-behavioral skills must be addressed in addition to disability and symptoms.

Patients want and are entitled to get the information they need, in both written and oral form. However, self-management and shared decision-making are important means to cope with the disease consequences. Interactive computerized patient education may be a valuable supplement today, also to improve cognitive-behavioral outcomes. Lorig developed and implemented patient education programs in arthritis on the basis of the concept of self-efficacy. Lorig's arthritis self-management programs (ASMPs) have been disseminated internationally, and evidence supports that increased self-efficacy mediates improvement in perception of control, health behaviors, and health status (grade A).^{4†}

A systematic review has shown that patient education has a greater beneficial effect on symptoms and health status than on disease activity and

[†]Evidence rated as "grade A*" represents data from systematic reviews and meta-analyses of randomized trials. If there is no systematic review and/or meta-analysis addressing the given issue, then the authors cite data from individual randomized controlled trials (grade A) to support the recommendations. Recommendations based on results from observational studies (grade B) and/or case series (grade C) is used only when data from randomized controlled trials are not available.

TABLE 98.1

Roles and areas of expertise of the potential members of a multidisciplinary team

Profession	Roles and areas of expertise
Clinical pharmacist	The clinical pharmacist identifies, solves, and prevents drug-related problems such as unnecessary drug use, nonoptimal drug or dosage, need for additional drug, interaction between drugs, adverse drug reactions, and need for more information or therapy discussion.
Nurse	The nurse assists the patient in the performance of health-promoting activities to meet needs when altered ways of self-care are required due to disease or treatment. Nurses focus on activities that the patient would perform unaided given the skill, will, or knowledge, and thus the mobilization, strengthening, or compensation of these resources. Optimal levels of physical, mental, and social coping and symptom relief are important targets.
Nutritionist/dietician	The nutritionist/dietician assesses, diagnoses, and treats nutrition-related problems and gives practical guidance regarding diets to individuals and to the public. He or she is qualified to treat a range of medical conditions with dietary therapy on the basis of current literature, scientific evidence, best practices, and the individual needs of the person.
Occupational therapist	The occupational therapist evaluates the impact of rheumatic diseases on function and performance of daily tasks and valued life roles, using interviews, observation, and standardized assessments. Personal goals, interests, and resources are screened to develop an individualized program aimed at assisting adjustment to new or modified life roles, and the home/school/work environment is assessed to determine if adjustments are necessary to enhance the person's abilities. The most important interventions in occupational therapy are patient education concerning ergonomic principles and energy conservation, therapeutic exercise and activity programs, provision of orthoses and assistive technology, and environmental and task modifications.
Orthopedic surgeon	An orthopedic surgeon trained in the treatment of people with rheumatoid arthritis is responsible for performing surgical procedures and, together with the patient, rheumatologist, and relevant team members, establishing a plan for surgical procedures that should be coordinated with the timing of other interventions.
Podiatrist/orthopedic shoemaker/orthotist	The orthopedic shoemaker evaluates the foot and ankle to define deformities, instabilities, and painful areas. Custom-made insoles, prefabricated orthopedic shoes, and custom-made shoes are common interventions in pain relief and stabilization of an unstable and/or painful rheumatoid foot and ankle. The orthotist can supply prefabricated or custom-made orthoses for all body parts to prevent or correct deformities, reduce pain, or increase function. Lightweight and soft materials with an easy closure system are preferred. Because rheumatoid arthritis usually affects multiple joints, it is important to have an overall and integrated view when planning the orthotic treatment.
Psychologist	The role of the clinical psychologist is to assist the patient and family in managing emotional and psychological stress and to assist in living and coping with a chronic disease. On the basis of an evaluation, the psychologist tailors a treatment plan to meet the needs of the patient. The clinical psychologist provides a wide range of interventions designed to enhance coping, including cognitive therapy; pain, sleep, and stress management; sexual and relationship counseling; and psychotherapy. The psychologist may also have a consultation role in the interdisciplinary team.
Physical therapist	The physical therapist assists patients in achieving optimal function, pain relief, and physical recovery. On the basis of an evaluation of physical and functional status, the physical therapist uses therapeutic exercises and manual techniques to improve patients' muscle strength, joint mobility, and cardiovascular function. Physical modalities such as heat, cold, electrical therapy, and hydrotherapy may also be used to achieve temporary pain relief and reduce muscle spasm, so that the patient is prepared for exercise and activity.
Rheumatologist	The rheumatologist is primarily responsible for diagnosis and the total management. His or her main responsibility is usually pharmacologic interventions and disease monitoring. The rheumatologist works with the patient and members of the multidisciplinary team to identify needs for nonpharmacologic interventions.
Social worker	The social worker plays a role in preventing and solving personal problems and problems regarding networks of interpersonal relations within and outside the family. He or she also addresses economic problems and limitations regarding education, work, and/or a professional career.

anxiety, and that the efficacy mostly is seen only at the first follow-up visit (grade A*) (Table 98.2).⁵ Another systematic review highlighted that educational programs improved knowledge and compliance without improving in health status, whereas psychoeducational programs improved coping behavior. Further, short-term effects in program targets were generally observed, whereas long-term changes in health status were not convincingly demonstrated (grade A*).⁶

Hewlett and colleagues have recently shown that a group cognitive-behavioral therapy program could improve fatigue impact and coping (grade A).⁷ Another recent randomized controlled trial was able to demonstrate that a mindfulness-based group intervention reduced psychological distress and fatigue in patients with inflammatory rheumatic joint diseases (grade A).⁸

Almost all persons with RA use medications, and in a Norwegian study, up to 60% of patients with RA or polyarthritis reported using five or more drugs when admitted to a hospital.⁹ Not surprisingly, issues concerning medication and adverse effects are frequently raised in studies exploring unmet health care needs in this patient population. Clinical pharmacists are educated to identify and prevent drug-related problems.⁹ Counseling with pharmacists should thus be available on an individual basis as well as in group-based patient education programs.

Joint protection is a self-management program that aims to maintain functional ability by teaching participants to use altered movement patterns, alternative working methods, assistive devices, and activity pacing.¹⁰ Studies of such programs using standard methods of information communication

and training have shown little or no effect. However, better results on several outcomes were observed in individuals with early RA who were exposed to a joint protection program based on educational-behavioral teaching methods compared with those who underwent a program based on traditional practice (grade A).¹⁰ This suggests that joint protection programs can help slow the progression of the effects of RA over and above the benefits of drug therapy alone.

In conclusion, patient education should be an integrated part of the total management of RA. Elements that focus on aspects like self-efficacy and coping behavior seem to increase the likelihood of an effect on symptoms and health status.

Nursing care

Nursing care for patients with RA includes providing emotional support for adaptation to the new diagnosis; knowledge about the disease, consequences, and treatment; and discussions on self-management in general and on symptoms. This type of care was previously performed only in the setting of hospitalization, but the principles are increasingly transferred into day care or outpatient clinics. It is not known whether nurse-led clinics can prevent or reduce the impact of the disease, but significant increases in patient satisfaction have been recorded (grade A).¹¹

Assessments in nursing care should address needs on the basis of what is most important to the patients. Pain, physical functioning, and fatigue

TABLE 98.2
Effect of patient education interventions on various outcomes at first and last follow-up visits

Outcome measure	First follow-up		Last follow-up	
	Exp/control (no.)	SMD (95% CI)	Exp/control (no.)	SMD (95% CI)
Pain	1119/1000	−0.08 (−0.16-0.00)	530/543	−0.07 (−0.019-0.05)
Functional disability	1153/1122	−0.17 (−0.25-0.09)	651/657	−0.09 (−0.20-0.02)
Joint count	585/573	−0.13 (−0.24-0.01)	484/490	−0.08 (−0.22-0.07)
Patient global assessment	181/177	−0.28 (−0.49-0.07)	302/316	−0.06 (−0.22-0.10)
Psychological status	561/577	−0.16 (−0.28-0.04)	392/402	−0.04 (−0.10-0.19)
Anxiety	671/657	−0.04 (−0.15-0.07)	481/509	−0.01 (−0.12-0.13)
Depression	899/871	−0.14 (−0.23-0.05)	564/579	−0.09 (−0.21-0.02)
Disease activity	326/321	−0.03 (−0.19-0.12)	359/359	−0.05 (−0.20-0.10)

Negative results favor patient education.

CI, confidence interval; Exp, experimental; no., numbers for experimental versus control intervention; SMD, standardized mean difference.

Modified from Riemsma RP, Taal E, Kirwan JR, Rasker JJ. Systematic review of rheumatoid arthritis patient education. *Arthritis Rheum* 2004;51:1045-59.

are the most frequently reported prioritized symptoms and areas of disease impact, and the recently developed Rheumatoid Arthritis Impact of Disease score may be helpful in identifying areas of particular importance to patients.¹²

The assessment of patients' own resources is central in nursing care. Nursing care aims to mobilize, strengthen, or compensate for deficiencies in dimensions of self-care. Importantly, the European League Against Rheumatism (EULAR) has recently published recommendations on the role of the nurse in the management of chronic inflammatory arthritis (grade A*).¹³

Physiotherapy

Physiotherapy, including exercise, hands-on techniques, and different physical modalities, is an important component of the nonpharmacologic care of people with RA.

Exercise

Patients with RA have been shown to have reduced muscle strength, endurance, and aerobic capacity compared with age-matched controls (grade B).^{14,15} Due to fear of aggravation of disease activity and symptoms, people with RA were earlier advised to limit the amount of physical activity and protect their joints when exercising physically. However, deconditioning and low muscle strength predict earlier mortality in both diseased and normal populations at levels of significance similar to or greater than biomedical predictors (grade B).^{14,15} In general, physical activity is associated with better physical and mental health, prevention of disease, and reduced risk of all-cause mortality, and based on consistent findings in the literature, aerobic and strengthening exercise are safe and beneficial for people with RA (grade A*).¹⁶⁻¹⁸ A systematic review of 14 randomized controlled trials encompassing 1040 RA patients found that cardiorespiratory aerobic exercise improved physical function (Health Assessment Questionnaire score), pain, and quality of life, and the authors concluded that cardiorespiratory exercise appeared safe for people with RA (grade A*).¹⁷ Further, a meta-analysis of 10 randomized controlled trials encompassing a total of 547 patients evaluated the efficacy of resistance exercises in RA patients and found that such training is safe and beneficial. Several measures of muscle strength and function improved, and subgroup analyses revealed a trend toward higher efficacy for high-intensity programs (grade A*).¹⁸

The effectiveness and safety of a high-intensity program was confirmed in a multicenter study in the Netherlands that included 300 RA patients (grade A).¹⁹ Compared with usual care, the high-intensity program was more effective in improving the functional ability of RA patients, and the progression of radiographic damage of the small joints of the hands and feet was not increased by the long-term, high-intensity, weight-bearing exercises (grade A).¹⁹

The beneficial effects and safety of exercise was also supported in a review of 15 clinical trials evaluating aerobic and strengthening exercises, which concluded that aerobic capacity and strength improved without negative effects on pain and disease activity (grade A*).¹⁶ Based on the results of this review, the authors provided the following recommendations for aerobic exercises: the intensity level should be moderate to hard (i.e., 60% to 85% of maximum heart rate), and exercises should be performed three

times weekly for a duration of 30 to 60 minutes. The recommendations are similar to those for the general population, except that the following special considerations may be necessary for people with RA:

- Careful progression of intensity and individual adjustments of the program may be necessary due to disease fluctuations and/or disease activity.
- Caution should be used because of increased risk of fractures due to osteoporosis or treatment with glucocorticoids.
- Patients with joint replacements should be careful with heavy loads.
- During periods of high disease activity, flexibility and range-of-motion exercises together with strength training of large muscles are preferred.

Most of the studies on the effects of exercise interventions involved patients with established, stable RA, but a randomized controlled study conducted in Finland included patients with early RA (grade A).²⁰ A strength training program was compared with a program of range-of-motion exercises, and during the 2-year training period, a statistically greater improvement in muscle strength and functional capacity occurred in the strength training group. The results of this study indicate that, in patients with early RA as well, dynamic strength training should be recommended. However, to maintain adequate joint flexibility, range-of-motion exercises should also be part of exercise programs for patients with RA, even if high-quality studies evaluating the effect of such exercises are lacking.

The increased risk of cardiovascular disease represents an excess burden of morbidity and mortality in RA patients (grade A*).²¹ A review of studies investigating exercise interventions in relation to cardiovascular disease in RA patients provided strong evidence that exercise of various modes from low to high intensity is effective in improving disease-related characteristics and functional ability in RA patients (grade A*),²² but future studies are required to investigate the effects of exercise in improving the cardiovascular status of this patient population.

In summary, dynamic exercises are safe and beneficial for patients with both early and established RA. For most patients, no harmful effects in terms of radiologic damage of the joints are reported, but patients with extensive joint damage should be careful with high-intensity weight-bearing exercises. The mode of exercising should be based on the individual patient's preferences, because there is lack of evidence on the optimal mode of exercise delivery (land or water based, group or individual) (grade A*).²³ Due to the increased risk of comorbidities such as cardiovascular disease, it is important that health professionals promote physical activity and guide patients in achieving and maintaining a healthy lifestyle.

Hands-on techniques and physical modalities

Several passive physiotherapy modalities are also frequently used in the management of RA, including joint mobilization or manipulative techniques, electrotherapy, thermal agents, and balneotherapy. Many RA patients prefer these treatment alternatives for pain control and increased joint mobility.

Patients with limited range of motion of peripheral joints may benefit from passive mobilization, but in general, the evidence for hands-on

techniques is scarce (grade A*).²³ Some physical modalities, like transcutaneous electrical nerve stimulation (TENS), therapeutic ultrasound, low-level laser therapy, and thermotherapy, have been recommended for the management of rheumatoid arthritis (grade A)²⁴ (see Chapter 47). TENS is used for pain control or muscle stimulation, and there are conflicting results on the effect of TENS on pain outcomes in patients with RA (grade A*).²⁵ More well-designed studies with a standardized protocol are needed to provide further evidence of the efficacy in RA (grade A*)²⁵ (see Chapter 47). Ultrasound in combination with some other treatment modalities (exercises, faradic current, and wax baths) was not found to be effective in a Cochrane review. However, some studies, mostly of poor quality, indicated that ultrasound alone applied to the hand may have a beneficial effect on grip strength, wrist motion, morning stiffness, and joint counts. No harmful effects have been reported (grade A*).²⁶ An updated review of the use of low-level laser therapy in people with RA concluded that this modality could be considered for short-term treatment for relief of pain and morning stiffness, particularly because it has few adverse effects (grade A*).²⁷

Superficial moist heat and cryotherapy can be used as palliative therapy. Paraffin wax baths combined with exercises can be recommended for beneficial short-term effects on arthritic hands, but the conclusions are limited by the poor quality of the trials (grade A*).²⁸ Similarly, there is insufficient evidence to support the use of balneotherapy. Although many studies report positive findings, the studies suffer from poor methodology and the results must be considered with caution (grade A*).²⁹

Hand exercises and orthoses

Many of the activity limitations seen in persons with RA are explained by impaired hand function, with grip force as the most important determinant.³⁰ Hand exercises are therefore a recommended strategy to improve hand function. In 2004 a systematic review concluded that there is some, but limited, evidence that long-term hand exercise may increase grip strength in patients with RA (grade A*).³¹ More recent studies have confirmed that intensive hand exercise programs are well tolerated and effective in improving hand function in terms of decreased pain and increased strength (grade B).³² However, more research is necessary to determine the optimal combinations of different kinds of exercises, variations in resistance, number of repetitions, and daily or weekly frequency for patients with early or established RA.

The wrists and finger joints are the most frequently involved joints in persons with RA. Thus hand splints or orthoses are often prescribed to reduce pain and/or swelling, prevent contractures and deformities, and increase joint stability. Working wrist orthoses, resting splints for the wrist and hand, and splints to correct specific deformities are three commonly used hand orthoses in RA (Fig. 98.1). A systematic review of the use of splints and orthoses for treatment of RA concluded that working wrist splints have no positive short- or long-term effect on pain, grip strength, or range of motion (grade A*).³³ Still, the authors recommended that patients try inexpensive, ready-made wrist orthoses because studies indicate that they may provide pain relief for some patients in some activities.

The authors of the systematic review of orthoses also concluded that current evidence does not allow recommendations to be made regarding the use of resting hand splints to reduce pain and swelling, even though patients in one of the two studies preferred wearing the splints to not wearing them (grade A*).³³

Small custom-made splints have been shown to correct deformities and improve pain³⁴ (grade A), whereas specially designed silver ring splints may improve dexterity in patients with swan neck or boutonnière deformity^{35,36} (grade B).

Foot orthoses, insoles, and orthopedic shoes

More than 85% of people with established RA have involvement of the joints in the foot, which can lead to pain, joint instability and deformities, walking difficulties, and limitations in performance of daily activities.³⁷ In addition, joint abnormalities in the foot may alter walking patterns and thereby the biomechanics of the entire lower extremity. Persons with RA are therefore advised to use appropriate footwear, such as light-weight running shoes or rocker shoes, and many also use foot orthoses, insoles, or orthopedic shoes to relieve foot pain and normalize gait. A variety of prefabricated and custom-made orthoses and shoes are available. Soft insoles made of viscoelastic materials may attenuate shock during walking; semirigid orthoses are made to promote a more uniform pressure distribution in the foot; and rigid foot orthoses are designed to reduce unwanted motion and maintain desired structural alignment. Orthopedic shoes are made with extra depth in the shoe box, greater foot stability, and/or padded heel collars for improved

Fig. 98.1 Hand orthoses may decrease pain and correct deformities. From top to bottom: a resting splint that restricts motion and maintains a functional position, a functional wrist splint that supports the wrist during hand activities, and a silver ring splint that corrects and/or prevents deformities.

fit. Often, a combination of orthopedic shoes, orthoses, and soles is used to achieve an optimal effect.

In general, current research supports the use of these interventions. The results of a systematic review of interventions for foot disease in RA indicates that shoes with extra depth have beneficial effects on pain and function and that the benefit is greater if the shoes are combined with orthoses (grade A*).³⁷ In a recent review, some evidence was found that custom foot orthoses may reduce pain and forefoot plantar pressures, and inconclusive evidence was noted for an effect of orthoses on foot function, walking speed, gait parameters, and the rate of progression of hallux valgus deformities (grade A*).³⁸ However, studies have not clearly shown which type of shoes or foot orthoses is most effective.

Assistive technology

Assistive technology is prescribed and used as a means to reduce pain and compensate for impairment and environmental demands, and it is one of the most frequently used self-help strategies reported by persons with RA.³⁹ It includes a wide range of products, from low-tech devices to technologically complex equipment; some of these are designed for the general population, whereas others have been developed to meet the needs of people with functional limitations or disabilities (Fig. 98.2). Studies indicate that two thirds of all persons with arthritis use assistive devices on a daily basis and that use of such technology is associated with more severe disease, longer disease duration, and loss of grip strength and functional ability. However, even if provision of assistive devices is a widely used multidisciplinary intervention, there is a general lack of studies evaluating the benefit of such devices. Only one small study assessing the effect of an eye drop delivery device met the inclusion criteria for a review of assistive technology use in RA (grade A*).³⁹ One reason for the small number of studies and low level of formal evidence may be that the effect of some assistive devices seems rather obvious, such as the benefit of using raised seats, grab bars, or canes or crutches to ease safe transfer or increase mobility.

Psychological interventions

Living with a persistent and chronic disease like RA may lead to psychological distress and reduced quality of life. Psychological interventions are

Fig. 98.2 Use of assistive devices is one of the most frequent self-help strategies reported by persons with rheumatoid arthritis. From left to right: an enlarged grip for opening bottles, a self-opening scissor tong, and a bread knife with an ergonomic handle.

therefore often used to improve pain, anxiety, and/or depression. These interventions may consist of one or a combination of modalities such as relaxation strategies (e.g., progressive muscle relaxation), biofeedback therapy for reduction of muscle tension, cognitive-behavioral strategies (e.g., cognitive reconstruction, pain coping), and patient education. Research indicates that these approaches may be effective adjuncts to conventional medical management. In a review based on data from 25 randomized controlled studies, statistically significant improvement was noted in pain, functional ability, depression, coping, and self-efficacy immediately following psychological treatment, but the effect sizes were small (grade A*),⁴⁰ and the effects were not maintained to the follow-up examinations performed at an average of 8.5 months. Subgroup analyses revealed that psychological interventions may be more effective in patients with shorter disease duration. These results were confirmed to a large degree in a more recent review in which psychological interventions also were found to have a significant positive impact on physical activity levels (grade A*).⁴¹

Nutrition

People with RA may try to replace their traditional food with special diets.⁴² The most common diets are vegetarian (usually eliminating meat and fish), vegan (eliminating meat, fish, eggs, and milk), Mediterranean (including small amounts of meat and more fish, fruits, vegetables, and olive oil), and elemental or elimination diets. Elemental diets are usually liquid diets containing nutrients that are broken down to make digestion easier, whereas elimination diets are used to exclude foods that might worsen the disease. A systematic review of dietary interventions in RA concluded that the effects of diet on pain, stiffness, and physical function were uncertain (grade A*).⁴² However, the results of one single trial indicated that both fasting followed by a vegetarian diet and a Cretan Mediterranean diet may improve pain compared with an ordinary diet, whereas the effects of vegan and elimination diets are uncertain (grade A*).⁴² Higher dropout rates and weight loss in the intervention groups also indicate that dietary manipulations have potential adverse effects.

Many dietary interventions are in line with what may be considered a healthy diet, with a focus on fiber, fruits, vegetables, antioxidants, fish, moderate amounts of lean meat, and reduction of saturated fat and sugar. In general, persons with RA should therefore be given the same advice as the general population, which is to follow a healthy diet, avoid certain foods that may cause allergies or intolerance, and consult a nutritionist if they want to try any special diet.

Vocational rehabilitation

Functional limitations may cause productivity loss in terms of work disability, work loss (synonymous with absenteeism or short-term sick leave), or work limitation (reduction in productivity while still present at work). A systematic review examining productivity loss due to RA showed that RA-related work disability rates were similar in the United States and European countries and that a median of 66% of employed RA patients had experienced work loss due to RA for a median duration of 39 days in the previous year (grade A*).⁴³ However, the time between diagnosis of RA and a 50% probability of being work disabled varied from 4.5 to 22 years. The results also showed that the prevalence of RA-related work disability has

decreased over time, which may be due to advances in drug treatment of RA, a general decrease in the proportion of people engaged in manual or physically demanding work, or changes in social policies, level of education, age, and disease duration (grade A*).⁴³

To enable persons with RA to maintain or return to work, multidisciplinary vocational rehabilitation programs have been developed (see Chapter 47). In the aforementioned systematic review, it was concluded that even though some positive effect of such programs on vocational status was demonstrated in five of the six studies included, the proof of the effect was limited because all included studies were uncontrolled trials and five had a retrospective design. Since then, a randomized controlled trial has demonstrated that targeted, comprehensive occupational therapy significantly improves functional and work-related out-comes in employed RA patients at risk of work disability (grade A).⁴⁴

Prevention of work disability is probably more effective than correction of work disability after work loss. One program included self-management group sessions combined with individual professional assessments and interventions, with a follow-up by telephone 1 month after patient completion of the program. As a consequence of the program, participants were more able to adapt their work to their arthritis, and improvements in fatigue, self-efficacy, and at-work productivity over 12 months were shown (grade B).⁴⁵ Another randomized controlled study examined job loss in individuals with early RA who were randomly assigned to receive adalimumab combined with methotrexate or methotrexate alone. The proportion experiencing job loss after 56 weeks was significantly lower in the group receiving combination therapy (grade A).⁴⁶ This current evidence indicates that more attention should be directed to rapid identification and treatment of persons at risk of being work disabled.

Team care involving multiple disciplines

In many countries access to a multidisciplinary team is considered a part of the standard care for patients with RA. However, access to services from health professionals differs and may be influenced not only by socioeconomic factors but also by factors such as awareness of doctors about treatment opportunities, availability of health professionals, existence of waiting lists, residence in rural areas, and insufficient funding for effective services.

A review of the effects of comprehensive rehabilitation concluded that inpatient and day patient programs were equally effective with regard to disease activity and functional ability (grade A*).⁴⁷ In many countries, a clinical nurse practitioner care model exists. Nurse practitioners have extended their roles to incorporate some of the services that usually have been offered by the rheumatologist or other health professionals, and the aim of nurse-led clinics is to assist in access to services and clinical communication for patients with rheumatic diseases. The number of studies evaluating clinical nurse practitioner models are few, but the clinical effectiveness of three different care models (care delivered by a clinical nurse specialist, inpatient team care, and day patient team care) were compared in one randomized controlled trial (grade A).⁴⁸ Care provided in nurse-led clinics produced similar clinical outcomes in terms of disease activity, functional ability, and quality of life compared with inpatient and day patient team care, but at a significantly lower cost. All patients reported high satisfaction with multidisciplinary care, although patients who attended a nurse-led clinic were slightly less satisfied than those who received inpatient or

day patient team care. Thus nurse-led clinics appear to be an effective innovation in the care of patients with RA, and the role of nurses is further emphasized in the recent EULAR recommendations (grade A*).¹³

The primary therapist model (PTM) is another transdisciplinary model in which specially trained health professionals assume the roles of case managers and health care providers rather than general therapists.⁴⁹ If it is considered safe, they will consult with their colleagues, rather than transfer a patient to the provider in the other discipline, for completion of a rehabilitation regimen. In this way, they transcend their professional boundaries and take on extended roles and responsibilities. The model has been tested in a randomized controlled study with 111 participants. Patients received 6 weeks of rehabilitation treatment consisting of either services from a primary therapist (PTM) or traditional care from physical therapists and/or occupational therapy (grade A).⁴⁹ After 6 months, a significantly greater proportion of patients in the PTM group showed a clinical response; the PTM group also showed a greater improvement in quality-adjusted

life-years, but the costs were higher. The authors concluded that the PTM has the potential to be an alternative to traditional physical and occupational therapy, and further research should focus on strategies to reduce the costs of the model and assess the long-term economic consequences in managing RA (grade A*).⁴⁹

In summary, team care, defined as care provided by a group of health professionals with different professional backgrounds, seems to be beneficial for patients with RA. Further, it appears that similar effects, but at lower costs, may be achieved by transdisciplinary models in which clinicians take on extended roles coordinating multidisciplinary care in an outpatient setting. Flexible models of care should be provided for patients with RA that meet the varying needs and preferences of people of different ages, genders, and life and disease stages. Future research should address the effect of the content and composition of the team care on relevant outcomes and identify patients and contextual factors that enhance or limit the efficacy of team care interventions.

PEDIATRIC RHEUMATOLOGY

99A

Evaluation of musculoskeletal complaints in children: clinical evaluation

■ NORA G. SINGER ■ ANGELO RAVELLI

- A systematic approach should be used to assess symptoms of musculoskeletal and rheumatic diseases in children.
- The physical examination is used to distinguish between inflammatory rheumatic and mechanical musculoskeletal diseases of children.
- Specific clinical maneuvers can be employed to identify the range of musculoskeletal disorders in children.

HISTORY TAKING FOR THE MUSCULOSKELETAL SYSTEM IN CHILDREN**General approach**

Children of all ages should be spoken to directly, honestly, and at an age-appropriate level. In this manner, verbal and nonverbal reassurance can be given, and at the same time the physician can explain what the visit will entail. For very young children, talking first to their parents while they are held in a parent's lap may reduce their fear. Major sources of anxiety for children and their parents include fear both of the unknown and of pain (such as might occur during physical examination or collection of specimens for laboratory testing). Telling a child what is required of him or her establishes trust in the long term even though it may be stressful at the initial encounter. How much of the history is reported by the parents and how much by the children themselves depends on the age of the child; adolescents should be engaged to provide their own history and require the opportunity at some point to be alone in the examination room without the parents. For younger children the sense of time and pain localization may be difficult to elicit directly from the patients themselves. Disparity in the historical narratives provided by the patient and the parent should be noted and may provide clues to the underlying problems. Discrepancies may be due to genuine mistakes, inaccurate recall, or errors of interpretation, or may be manifestations of a serious underlying issue, such as abuse. Child abuse at any level (physical, psychological, or sexual) may present as rheumatic complaints, particularly musculoskeletal pain.

Constitutional features

Most chronic inflammatory diseases are accompanied by a constellation of relatively nonspecific but potentially important constitutional features, such as lethargy and/or fatigue, mood change, irritability, reduced appetite, and weakness. Fever is a prominent indication of inflammation and may be typical, as in the evening fevers of systemic arthritis, or episodic, as in periodic fever syndromes such as familial Mediterranean fever or tumor

necrosis factor receptor-associated periodic syndrome. More chaotic or less localizing fever may be seen in disorders such as systemic lupus erythematosus. Complaints of muscle weakness are common in inflammatory myopathy, whereas complaints of muscle pain may be more profound in infectious and postinfectious inflammatory myopathy (e.g., pyomyositis, influenza associated myopathy) and may be seen in juvenile dermatomyositis. Absence of weakness may point toward complex regional or generalized pain disorders, whereas proximal muscle weakness typifies myopathy in chronic inflammatory disorders.

Joint pain

Joint pain is a key clinical feature of the history, and its description should include whether it interferes with function (e.g., walking, running, or writing), aggravating and relieving factors, diurnal variation, and progression. Pain reporting can be improved through use of an age-appropriate visual analogue scale such as one with happy and sad faces and may also be deduced by observing a child's pain avoidance behavior, for example, limping in the absence of pain complaints. Enlisting the parent's assessment of pain complaints is important, as is exercising caution in interpreting dramatic complaints of musculoskeletal pain by either the parent or the patient because pain also has an affective (psychological) component. The pain associated with inflammation tends to be mild to moderate in intensity (Table 99A.1), whereas the pain of infection is, in general, severe.

Joint swelling and stiffness

Any reported history of joint swelling should be assessed and confirmed during the physical examination (see later). Joint stiffness, the reporting of reduced, uncomfortable range of joint movement, seems to be at its worst on awakening in the mornings ("early morning stiffness") and improves throughout the day in inflammatory arthritis. "Gelling" may occur after prolonged inactivity, such as sitting in a car or at a desk.

EXAMINATION OF THE MUSCULOSKELETAL SYSTEM**General examination**

The child's general condition and appearance, including recorded growth and percentiles, skin color and condition, overall nutritional status, muscle bulk, vital signs (temperature, blood pressure), and joint movement when playing, can help in forming an overall assessment of whether the child is well or sick (Table 99A.2). Careful assessment of the eyes and peripheral pulses should also be included as part of the routine physical examination of these children.

TABLE 99A.1

Relative contribution of musculoskeletal clinical features in differential diagnosis in children

	Inflammatory disease	Mechanical disorder	Amplified pain disorders
Pain*	+/-	+	+++
Joint stiffness	++	+/-	+
Joint swelling	+++	+/-	+/-
Joint instability	+/-	++	+/-
Sleep disturbance	+/-	-	++
Physical signs†	++	+	+/-

*May depend on both the age of the child and the age appropriateness of the tool used to measure pain.

†Changes in temperature may be found in inflammatory disease and in amplified pain disorders but are more frequently accompanied by complaints of dysesthesia in the latter. From Southwood TR. Evaluating musculoskeletal and rheumatic disorders in children. In: Hochberg M, Silman AJ, Smolen JS, et al, editors. Rheumatology. Philadelphia: Mosby; 2007, p. 961-73.

TABLE 99A.2

Functional musculoskeletal examination

Position	Musculoskeletal features examined
Sitting cross-legged	Hip abduction, external rotation and flexion, knee flexion
Rising to stand straight	Leg extension, back extension, lower limb muscle power
Bending forward	Anterior spinal curvature, scoliosis
Removing shoes and socks	Hip and knee flexion, hand and wrist function
Removing top	Shoulder and elbow range of movement
Walking normally	Gait phases: stance, toe off, swing, heel strike
Tiptoe walking	Toe extension, ankle plantar flexion, muscle power
Heel walking	Ankle dorsiflexion, knee extension, pain at entheses
Hands pronated, arms extended	Elbow extension, shoulder power
Making a fist	Finger flexion
"Hands praying" position	Wrist extension, elbow flexion, finger extension
Arms above the head, reaching	Shoulder flexion
Looking over each shoulder	Cervical spine rotation

From Southwood TR. Evaluating musculoskeletal and rheumatic disorders in children. In: Hochberg M, Silman AJ, Smolen JS, et al, editors. Rheumatology. Philadelphia: Mosby; 2007, p. 961-73.

Joint assessment

Conducting a standardized joint examination minimizes the risk of omission (a side-to-side comparison should always be made). Head-to-toe joint examination commonly is performed so that one will remember to examine all joints; starting by examining the extremities may be less threatening to the young child.

Suggested steps in the joint examination include the following:

1. **Look:** Inspect the position of the joint at rest, its surface anatomy, contours, color, scar, size and muscle bulk, and limb length.
2. **Feel:** Palpate for skin warmth, joint swelling, and tenderness. Swelling includes any increase in joint size that alters the normal surface markings of the joint. The key sites for observing swelling depend on the particular joint and the nature of the swelling itself. Swelling may be due to intraarticular effusion, periarticular fluid, soft tissue changes (edema; joint capsule thickening; inflammation of muscle, ligament, and/or subcutaneous or cutaneous tissues), or bony hypertrophy. Joint margin tenderness and/or tenderness and inflammation at the site of tendon insertion into bone or ligament, fascia, or joint capsule may indicate the presence of enthesitis.

Fig. 99A.1 Relaxed passive extension of the knees. The right knee has subtle loss of relaxed passive extension indicating loss of joint range secondary to juvenile idiopathic arthritis. (From Southwood TR. Evaluating musculoskeletal and rheumatic disorders in children. In: Hochberg M, Silman AJ, Smolen JS, et al, editors. Rheumatology. Philadelphia: Mosby; 2007, p. 961-73.)

3. **Move:** Include motion by the examiner (passive range of motion) and by the patient (active range of motion), noting any pain or irritability on motion, especially at the end range of joint motion.
4. **Test:** Assess joint stability, particularly for the stability ligaments of the knee (cruciate and collateral ligaments), and assess for pain referable to other joint structures such as the menisci and associated structures such as the iliotibial bands and bursa.

In young children, beginning the examination with the toes and feet is the least upsetting. Examining the most painful areas at the end of the examination often facilitates performing a complete examination.

Feet and ankles

With the child supine, observe the leg lengths carefully for any discrepancy. Asking the patient to curl his or her toes allows observation of flexion and extension metatarsal and interphalangeal joint movement. Carefully squeeze the metatarsophalangeal joints in such a manner as not to cause alarm, and if tenderness is noted, assess each metatarsophalangeal joint for synovitis by gently palpating the joint margins while moving the joint through its range of motion. Examine the midtarsal joints by stabilizing the calcaneus while inverting and evertting the forefoot. Assess the subtalar joints by inverting and evertting the calcaneus (hindfoot) and the ankle (tibiotalar) joints by dorsiflexion and plantar flexion at the ankle to detect synovitis. Synovitis is sometimes appreciated only when observed posteriorly; observation from the posterior view also allows detection of Achilles tendon thickening. To detect enthesitis palpate for tenderness at the insertion of the plantar fascia to the metatarsal heads, fifth metatarsal base, calcaneus, and Achilles tendon insertion into the posterior aspect of the calcaneus.

Knees

Loss of vastus medialis muscle bulk and/or bulk in the gastrocnemius may result from muscle atrophy due to reduced use and/or guarding of a painful joint. Subtle loss of knee extension may be seen using relaxed passive extension of both knees by lifting the patient's feet gently up off the table (Fig. 99A.1). Mild swelling obscuring the medial and lateral contours of the patella can be confirmed by palpating and inspecting for a synovial fluid wave or bulge sign (medial compression followed by lateral "reexpression" of the swelling) and by balloting the patella. Joint margin tenderness is often maximal just medial to the lower patellar border. Key points for palpation of entheses are at the tibial tuberosity and the 2, 6, and 10 o'clock positions around the patella. Knee locking or giving way may indicate a mechanical disorder and requires assessment of knee stability. The most useful examination techniques for medial and lateral collateral ligament integrity are the application of gentle valgus and varus pressure, respectively, on the knee (while the knee is held in 5 degrees of flexion), which may result in abnormal abduction or adduction (Fig. 99A.2). The anterior cruciate ligament is also vulnerable to sports injuries in children and young people; that, and the posterior cruciate, can be assessed using anterior and posterior drawer tests. These and other tests to elicit derangement or tightness of structures in and around the knee are listed in Table 99A.3.

Fig. 99A.2 Valgus stressing (a) and varus stressing (b) performed to detect any abnormalities in the medial and lateral collateral ligaments of the knee.

TABLE 99A.3

Maneuvers that may be used to diagnose mechanical disorders of the knee

Maneuver name	Structure(s) tested	Description
Patellar apprehension	Patella (laxity)	Knee is placed in relaxed flexion (30 degrees) and the patella is subluxed laterally using gentle pressure (not so much pressure that it could displace the patella).
Lachman	Anterior cruciate ligament (ACL) (integrity)	Knee is flexed to 20 degrees; the examiner holds the distal thigh above the knee, pressing down with that hand while simultaneously grasping the tibia with the other hand and pulling it forward. Excess motion or no sharp stop compared with the other side indicates possible injury to the ACL.
Anterior drawer	ACL	Knee is flexed to 90 degrees with foot stabilizing the knee. The proximal tibia is held with both hands, thumbs in front reaching circumferentially; the tibia is displaced anteriorly. Excess laxity compared with the other side is considered a positive finding, although asymmetric pain and any abnormal movement should be noted.
McMurray	Menisci	With a thumb and fingers placed over the medial and lateral joint line, the knee is moved through range of motion by holding the foot with the other hand and applying medial or lateral rotational pressure. The knee is extended passively and the procedure repeated to detect pain at the joint line. Pain, sometimes accompanied by a “thunk,” suggests the presence of meniscal abnormality.
Valgus stress	Medial collateral ligament (MCL)	With the knee extended, the upper hand is placed above the knee laterally and the lower hand over the gastrocnemius on the medial aspect. Pressure is applied outward on the calf, and laxity and pain are noted if the MCL is not functioning normally.
Varus stress	Lateral collateral ligament (LCL)	With the knee extended, the upper hand is placed above the knee medially and the lower hand over the gastrocnemius laterally. Pressure is applied inward on the calf, and laxity and pain are noted if the LCL is not functioning normally.
Posterior drawer	Posterior collateral ligament	Performed in the same manner as the anterior drawer test except that the tibia is forced posteriorly.
Ober test	Iliotibial bands	Patient is placed on the nonpainful side. The affected hip is placed in a slightly extended position with the hip flexed and pain or limitation is observed when the affected leg is no longer held in the air by the examiner but instead returns to the surface.
Thomas test	Quadriceps (flexibility)	A hand is placed under the lumbar lordosis and the patient is asked to flex one knee to the chest; if the other hip flexes, tightness of the quadriceps is suggested.

Hips

Detection of intraarticular effusion requires ultrasonography or magnetic resonance imaging. Screening for hip disease on examination is accomplished by passive internal and external rotation with the hip and knee flexed at 90 degrees; at least 45 degrees of internal rotation can usually be elicited in a normal child's hip. Extension range, which is normally 30 degrees beyond neutral when the patient is lying prone, tends to be lost early in hip arthritis, whereas loss of flexion in the hip generally indicates more advanced disease. Enthesitic points to be examined include the greater trochanter and anterior superior iliac spines.

Hands and wrists

Hand and wrist examination begins with a child sitting up with hands held out in front of the body. Begin by inspecting the dorsal aspect of the hands and fingers and eliciting active finger flexion by asking the child to “make fists” and “bury the fingernails” (Fig. 99A.3) (nail pitting may predate or accompany psoriasis). Joint swelling can be palpated with the hands in a prone position, and joint margin tenderness and passive range of joint movement also noted. Rotation of the wrists at the distal radioulnar joint allows inspection of the palmar surfaces of the hands and fingers. Active finger flexion at the interphalangeal joints should normally result in the fingertips making contact with the palms overlying the metacarpal joints. By using

Fig. 99A.3 “Burying the fingers.” Being able to perform the maneuver suggests the presence of normal flexion at the second through fifth metacarpophalangeal (MCP) joints, proximal interphalangeal joints, and distal interphalangeal joints. Some examiners have children make a full fist and also assess the first MCP and interphalangeal joint at the same time.

Fig. 99A.4 Asymmetric mouth opening and an abnormally small oral aperture due to mandibular hypoplasia and temporomandibular joint arthritis in a young adult who has had juvenile idiopathic arthritis since the age of 1 year.

the “prayer” position with palms placed together, finger flexion or wrist extension deformities can be detected, which has the advantage of highlighting asymmetry at the wrists and small joints of the hand.

Elbows and shoulders

The elbows are extended fully with hands reaching toward the ceiling (sometimes called *reaching for the sky*, which also demonstrates shoulder flexion) and then are lowered in an extended position to allow palpation of the olecranon bursa itself (which rarely swells in children except in injury or infection) and either side of the olecranon process. Functional elbow flexion can be demonstrated by placing the hands to the mouth. Pronation and supination of hands with the elbows at 90 degrees of flexion may reveal disruption of the proximal radioulnar joint. Assessment of the glenohumeral joint itself may proceed by palpating the joint margin with the humerus abducted to 90 degrees and rotated internally and externally (using the forearm as a lever down and up, respectively). The sternoclavicular joints should be palpated for tenderness and/or swelling.

Cervical spine and temporomandibular joints

Detection of limitation or loss of motion in the cervical spine and temporomandibular joints may raise the possibility of systemic arthritis, even if the child does not have complaints specifically referable to these joints (e.g., a teenager with ankylosing spondylitis as a cause of hip joint space narrowing may complain of hip pain but also have restricted neck motion). Lateral rotation and extension are most likely to be lost early if the cervical spine is affected by arthritis. Rotation can be evaluated by asking the patient to place the chin on each shoulder. The normal extension range on tipping the head back is greater than 20 degrees. Having the child place the ear on the shoulder allows assessment of lateral flexion. The face should be inspected for asymmetry or mandibular hypoplasia (Fig. 99A.4). The temporomandibular joints can be palpated just anterior to the tragus of the ear, where tenderness may be demonstrated and asymmetric movement detected, particularly on asking the patient to open the mouth widely (see Fig. 99A.4). An oral aperture below 40 mm is considered to be abnormal.

Spine and gait

The spine is best examined with the patient standing on bare feet and viewed from behind. Observe the position of the feet for loss of medial longitudinal arch contour (pes planus) and the hindfoot for overpronation, which suggests hypermobility (Fig. 99A.5). Check that the pelvis is horizontal; leg-length discrepancy is best detected clinically when the patient is standing. Assess for scoliosis by noting the symmetry of the spine in standing and gentle forward flexion (Fig. 99A.6). Palpation over the sacroiliac joints may reveal tenderness, although this maneuver may be insensitive for detection of inflammation. Checking particularly for abnormal flattening of the lumbar spine, which might suggest spondylitis, is important. Pain on hyperextension of the spine, which puts the only synovial joints (the apophyseal joints) in the spine on the stretch, can be seen in sacroiliac joint disease or spondylolysis. Gait should be assessed when the patient is wearing shorts and walking with bare feet. Note is made of each of the gait phases (heel-strike, stance, toe-off, and swing phases), with observation for antalgia, Trendelenburg abnormality (a waddling gait caused by weakness of hip stability muscles), and any other asymmetry.

Fig. 99A.5 Overpronation of both ankles associated with hypermobility. (From Southwood TR. *Evaluating musculoskeletal and rheumatic disorders in children*. In: Hochberg M, Silman AJ, Smolen JS, et al, editors. *Rheumatology*. Philadelphia: Mosby; 2007, p. 961-73.)

DIFFERENTIAL DIAGNOSIS

When a diagnosis of musculoskeletal or rheumatic disease is considered in a child, the history is of principal importance in distinguishing whether the complaints or physical findings are more likely related to congenital or acquired abnormalities of the developing musculoskeletal system or due to autoinflammatory or autoimmune disorders with tissue-specific manifestations. In children, overdiagnosis of mechanical musculoskeletal “disorders,” such as the variations in normal alignment in the growing skeleton, can be avoided through recognition of normal findings during an examination. Prompt recognition of abnormalities is key, because delay in diagnosis of either inflammatory disease or mechanical disorders may also delay appropriate and timely therapy.

Transient musculoskeletal complaints are common in children and adolescents and are often associated with sports-related conditions or non-rheumatologic disease. When present, systemic symptoms such as fever, rash, headache, listlessness or lethargy, limping, weakness, anorexia, or pain, which may be transient or chronic, should lead the examiner away from primary mechanical and noninflammatory disorders as the cause of the complaints. Knowledge of features that may distinguish inflammatory from noninflammatory conditions (see Table 99A.1) and a fundamental understanding of the spectrum of pediatric diseases that primarily involve other body systems but are known to have musculoskeletal manifestations (Table 99A.4) also help to focus the diagnostic strategy. Astute clinicians incorporate symptom combinations into their clinical reasoning rather than depending on isolated symptoms or laboratory examinations to arrive at a correct diagnosis. Disease features such as peripheral joint swelling increase the likelihood of a rheumatic diagnosis, whereas demonstration of joint instability, pain with maneuvers to isolate specific structures, and the absence of

Fig. 99A.6 Gentle forward flexion of the spine in a preadolescent boy who had normal examination findings.

TABLE 99A.4

Some major pediatric diseases that may have musculoskeletal manifestations

Disease	Musculoskeletal manifestation
Cystic fibrosis	Large and small joint arthropathy
Down syndrome	Carpal osteolysis
Diabetes	Cheiroarthropathy
Hypothyroidism/hyperthyroidism	Musculoskeletal pain
Hemophilia	Intraarticular and muscle hemorrhage
Hemoglobinopathies	Avascular necrosis, septic arthritis
Pancreatitis	Osteolytic lesions
Inflammatory bowel disease	Erythema nodosum, large-joint arthritis, spondyloarthritis
Cyanotic congenital heart disease	Hypertrophic osteoarthropathy
Malignancies	Metastases, hypertrophic osteoarthropathy

From Southwood TR. Evaluating musculoskeletal and rheumatic disorders in children. In: Hochberg M, Silman AJ, Smolen JS, et al, editors. Rheumatology. Philadelphia: Mosby; 2007, 961-73.

local inflammation and/or systemic symptoms are more suggestive of non-inflammatory rheumatic disease (see Table 99A.3).

Evaluation of musculoskeletal complaints in children: nonautoimmune musculoskeletal disorders

■ NORA G. SINGER

- Regional syndromes affecting the lower limb joints, particularly the hip and knee, are the most important nonautoimmune musculoskeletal disorders in children.
- Legg-Calvé-Perthes disease and slipped capital femoral epiphysis are important causes of hip pain in children.

INTRODUCTION

Understanding the spectrum of musculoskeletal disorders that occur in different age groups is helpful in focusing the clinician on a working diagnosis because childhood musculoskeletal diseases may be identified in part by the age at which symptoms appear. The acronym **ARTHRITIS**, proposed by Taunton Southwood, is a helpful mnemonic ([Box 99B.1](#)). The most important noninflammatory disorders and the typical age at which they occur are described in this chapter and are listed in [Table 99B.1](#), along with the symptoms with which they may present and important clinical features that help to distinguish them.

ARTHRITIC DISORDERS

In addition to juvenile idiopathic arthritis, there are other, typically acute forms of arthritis that are important in childhood.

Septic arthritis

Septic or infectious arthritis is a serious infection that should be recognized promptly because it can rapidly lead to joint destruction, sometimes within 24 hours of onset. Monarticular disease is much more common than polyarticular disease in infections with most organisms; the exception is *Neisseria* infection, especially gonococcal arthritis in teenagers. The hip joint is the most commonly septic joint in young children, and septic arthritis more frequently affects boys than girls. *Staphylococcus aureus* is now the most common bacterium causing septic arthritis; routine use of *Haemophilus influenzae* vaccine has drastically reduced the incidence of *H. influenzae*-related invasive disease. In the setting of congenital or acquired immunodeficiency (including sickle cell disease), suspicion of septic arthritis is increased. Children with infected joints generally look unwell and sometimes have a “toxic” appearance, with high fever and severe pain limiting the ability to bend the affected joint. Septic arthritis usually results from hematogenous spread but may also occur after a puncture wound or infected skin lesions (e.g., chickenpox). In young children, it may result from spread from adjacent osteomyelitis into joints where the capsule inserts below the epiphyseal growth plate; coexistent osteomyelitis occurs in up to 15% of affected children. Aspiration of the affected joint space for fluid analysis (the definitive test) and drawing of blood for cultures is best performed before intravenous antibiotics are started unless doing so would delay therapy unacceptably.

Reactive or postinfectious arthritis

Reactive arthritis is the most common form of arthritis in childhood and is defined as time-limited joint swelling (usually lasting less than 6 weeks) following (or rarely accompanying) evidence of extraarticular infection. The enteric bacteria (*Salmonella*, *Shigella*, *Campylobacter*, and *Yersinia*) are implicated in most pediatric cases of reactive arthritis. Arthritis following infection with parvovirus B19, influenza viruses, coxsackieviruses, *Mycoplasma*, or *Borrelia* or after infection with or vaccination against rubella virus or herpesviruses is also seen. Whether persistence of infection or immune response to prior infection drives ongoing symptoms in chronic Lyme arthritis and some postviral arthritides is still controversial. Acute rheumatic fever and poststreptococcal reactive arthritis may be classified within the broader category of reactive arthritis. If *Streptococcus*-associated joint symptoms occur when the original streptococcal infection was not recognized or treated, then antibiotic therapy is used to eradicate the organism and is indicated along with symptomatic treatment with nonsteroidal antiinflammatory drugs (NSAIDs) or, less commonly, salicylates.

MUSCULOSKELETAL SYNDROMES

Musculoskeletal syndromes may be general, affecting a number of joint areas, or specific to particular joint sites. Hypermobility syndrome is one of the most common noninflammatory diagnoses in children and is discussed in Chapter 210.

Benign limb pains

Benign limb pains, also known as *growing pains*, occur in 10% of children between the ages of 4 and 14 years. The relationship with growth is uncertain because this period is not the time when maximum linear growth occurs. Children typically awaken at night with deep thigh or calf pain that responds to analgesics, massage, and heat, and there may be a family history of similar problems in one of the parents. Normal findings on physical examination along with a history of normal activity once the episode resolves are helpful in distinguishing benign limb pain from a more serious cause of night pain (e.g., osteoid osteoma or malignancy-associated limb pain). No further workup is needed if there is a typical history and absence of any physical abnormalities. Atypical presentations may require further workup to exclude more serious problems. Growing pains frequently remit, although intermittent night pain may continue for many years.¹

REGIONAL SYNDROMES: HIP

Developmental dysplasia of the hip

Developmental dysplasia of the hip (DDH) is a spectrum of disorders with a number of predisposing factors: family history of DDH, female gender, first-born birth order, breech presentation, and oligohydramnios. Early detection, institution of corrective treatment, and prevention of long-term disability are the aims of routine screening programs at birth and the routine

6-week postnatal checkup; however, the evidence level to justify screening and intervention is fair to poor, and the issue is confounded by the knowledge that, in a substantial proportion of hips initially labeled as having DDH, the abnormality will resolve spontaneously without intervention.² The techniques of examination vary but usually involve examining one hip at a time while steadying the contralateral pelvis with the other hand. The upper portion of the femur is carefully rocked back and forth to check whether the hip can be dislocated posteriorly out of the acetabulum (Barlow maneuver) or relocated back into the acetabulum on abduction (Ortolani maneuver). It is important not to exert excessive force during these maneuvers. Asymmetry of skinfolds around the hip may be observed later in childhood. Limited abduction of the hip, shortening of the affected leg, or a limp or abnormal gait may also be seen with congenital hip disorders. A radiograph

supporting the diagnosis of DHH is seen in Fig. 99B.1. Ultrasonographic screening of all neonates is highly specific for detecting the condition but is expensive and has a high rate of false-positive findings. Orthopedic consultation is indicated if DHH is suspected. The affected infant may be placed in a positioning device to put the hips in abduction for several months. Progress is then monitored by ultrasonography or radiography. If the hip has not stabilized or the condition is diagnosed late, hip abduction using traction and a further period of splinting (in a plaster hip spica) may be

BOX 99B.1 AN APPROACH TO THE DIFFERENTIAL DIAGNOSIS OF RHEUMATIC CLINICAL FEATURES IN CHILDREN AND YOUNG PEOPLE

Avascular necrosis, orthopedic diseases (e.g., slipped upper femoral epiphysis, osteochondritis)

Reactive arthritis

Trauma associated, including nonaccidental injury and hypermobility

Hematologic: bleeding diatheses, hemoglobinopathies

Rickets and other metabolic and endocrine diseases: diabetes and thyroid diseases

Infection of bone or joint

Tumor, leukemia, neuroblastoma

Idiopathic/psychosomatic disorders, including musculoskeletal pain amplification syndromes

Systemic connective tissue diseases: multisystem inflammation of muscle, skin, blood vessels

Fig. 99B.1 Developmental dysplasia of the left hip with failure of acetabular formation and “telescoping” of the left femur.

TABLE 99B.1

Noninflammatory musculoskeletal disorders: symptom combinations and pivotal clinical features

“Typical” symptom combinations	Pivotal clinical features	Possible diagnoses
“Clunk” on hip movement screening, limping in an older infant	Asymmetric upper leg skinfolds, limited hip abduction	Developmental dysplasia of hip
Nocturnal awakening with leg pain in a young child	Normal child	“Growing pains” Osteoid osteoma
Sudden limping in an otherwise well young child	Unilateral restricted hip movement	Toxic synovitis
Joint effusion with or without pain	Effusion with hemorrhagic fluid on aspiration	Hemarthrosis after trauma or if recurrent Pigmented villonodular synovitis
Hip pain in a preadolescent (boys more than girls)	Loss of joint range, pain on motion, may be bilateral	Legg-Calvé-Perthes disease
Hip pain in an obese preadolescent boy	Unilateral hip restriction	Slipped upper femoral epiphysis
Hip pain and limp in adolescent girl	Unilateral pain and stiffness	Idiopathic chondrolysis
“Snapping” hip	Sensation of internal or external hip	Internal movement of the iliopsoas muscle over iliopectineal eminence, lesser trochanter, or anterior superior iliac spine; external movement of the iliotibial band over the greater trochanter hip
Localized pain	Point tenderness with or without localized swelling	Stress fracture
Anterior knee pain	Pain with use of stairs (ascending or descending), stiffness Tenderness over the tibial tuberosity Tenderness over inferior pole patella	Patellofemoral syndromes Osgood-Schlatter disease (apophysitis of the tibial tuberosity) Sinding-Larsen-Johansson syndrome Apophysitis of the inferior pole of the patella
Lateral knee pain	Pain over patellar tendon or quadriceps tendon Pain where iliotibial band courses over lateral femoral epicondyle; also may radiate proximally into iliotibial band Pain over lateral joint line, possible positive finding on McMurray test	Extensor tendinitis Iliotibial band syndrome Lateral meniscal injury
Medial knee pain	Intermittent pain and effusion with or without locking, usually increased with activity Popping or snapping medially when extending from flexion Pain inferior to medial joint line/tibia	Osteochondritis dissecans Medial plica syndrome Pes anserine bursitis

Fig. 99B.2 Ultrasound image in a patient with irritable hip (transient synovitis of the hip) demonstrating effusion.

tried. Weight bearing on a dislocated hip is avoided because of concern that it may further damage the femoral head and acetabulum. Open reduction and derotation femoral osteotomy are required if conservative measures fail. A risk of aseptic necrosis of the femoral head has been reported with both closed and surgical procedures, although it is a rare complication.

Transient (toxic) synovitis (irritable hip)

Toxic synovitis is the most common cause of acute hip pain in children. It occurs in children aged 2 to 12 years and often follows or occurs at the time of a viral infection. The syndrome most commonly presents with the sudden onset of pain in the hip and a reluctance to weight bear in the young child or a limp in the older one. There may not be pain at rest, but there typically is decreased range of motion; the hip is held in external rotation, which is the position of greatest comfort, and the pain may be referred to the knee. Fever may be present but is typically mild, and the affected child does not appear overly ill. The neutrophil count and levels of acute-phase reactants may be normal or slightly elevated and radiographic findings are normal, but a small joint effusion is frequently apparent on ultrasound evaluation (Fig. 99B.2). The most important differential diagnosis is septic arthritis, but this is usually distinguished from the more benign transient synovitis by the presence of high fever, severe illness, pain at rest, minimal or no movement of the hip, marked elevation of the neutrophil count and acute-phase reactant levels, and frequent association with positive blood culture results. Aspiration of the hip joint allows infection to be excluded and may temporarily relieve most or all of the symptoms. Management of transient synovitis is with NSAIDs; there is no definitive evidence indicating whether rest or activity as tolerated influences its course because it usually improves within a few days. Occasionally transient synovitis is assumed to underlie the presentation of Legg-Calvé-Perthes disease or slipped capital femoral epiphysis.

Legg-Calvé-Perthes disease

Legg-Calvé-Perthes disease (LCP) was described independently by Legg, Calvé, Perthes, and Waldenström.³ It is an idiopathic hip disorder hypothesized to be caused by reduced vascular flow to the affected area. It is more common in boys than in girls with a peak incidence between 4 and 10 years of age; onset is insidious with the disorder manifesting as a limp or persistent hip or knee pain. Up to 13% of children have bilateral involvement, and often the second hip is asymptomatic.³ When bilateral, the hips are usually in different stages of disease. Ischemia is thought to occur within the femoral epiphysis, but damage may be cumulative with more than one episode of ischemia leading to the observed avascular necrosis. Revascularization and reossification follow over 18 to 36 months, and the goal of treatment is to have the femoral head remodel in a spherical fashion within the acetabulum. Mutation in the *COL2A1* gene (which encodes a precursor of the type II collagen $\alpha 1$ chain) has been associated with LCP.^{4,5} The severity of hip involvement and long-term risk is similar in boys and girls; fever and elevated inflammatory parameters are typically absent.

Imaging

Initial radiographic findings may be normal, but radiographs eventually show increased density in the femoral head, which subsequently becomes

Fig. 99B.3 Avascular necrosis of the right hip.

fragmented (Fig. 99B.3) during revascularization and irregular, which results in superior and lateral subluxation. By 3 to 6 months after symptom onset, the proximal femoral epiphysis is smaller and denser than normal and the joint space wider than in the normal hip. On radiographs four stages of the pathologic process can be identified: initial, fragmentation, healing, and reossification. Healing is manifested by new bone formation and reossification, with or without residual deformity. Changes in the acetabulum are important in the long term, and the radius of the acetabulum may be the most sensitive measurement to detect the pathologic changes.^{6,7} At least two radiographic classification systems for LCP exist and are based either on the extent of involvement of the femoral head (Stulberg classification)⁸ or on the height of the lateral epiphysis on anteroposterior radiographs (lateral pillar classification system); the latter system appears to be more reproducible.⁹

In LCP, the amount of femoral head involvement and the degree of lateral subluxation are such important prognostic factors that assessment often requires magnetic resonance imaging (MRI), which is superior to conventional radiography and bone scanning in determining the extent and location of involvement in the femoral head and the degree of lateral subluxation.¹⁰⁻¹³

Before the advent of MRI, technetium-based bone scanning was the gold standard for evaluation of this disease; reduced uptake occurs initially followed by foci of increased accumulation in the femoral head as revascularization occurs; bone scanning may still be useful in situations in which MRI scans cannot be obtained (Fig. 99B.4b).

MRI adds additional anatomic visualization in LCP. Early on there is low signal intensity in T1-weighted images and an area with a secondary double line of low and high signal intensity on T2-weighted images. Widening of the medial joint space may be due to more than one mechanism. The presence of a subchondral fracture line on MRI predicts eventual necrosis better than it does the extent of necrosis.¹⁰ Gadolinium-enhanced subtraction MRI can improve sensitivity in early diagnosis of LCP and may be used to monitor subluxation.¹³ Synovitis was observed by MRI in 72 LCP patients, with a correlation between the severity of the synovitis and the severity of the necrosis.¹³⁻¹⁵ Cartilaginous physeal and metaphyseal abnormalities are common and frequently are associated with growth arrest.

Pathophysiology

Ischemic necrosis precedes collapse of the head and subsequent repair of the femoral capital epiphysis. The initial event is silent clinically, and with collapse and repair of the bone, pain and limitation of motion, particularly abduction and internal rotation, develop to varying degrees.^{7,11} The extent of subsequent growth disturbance of the proximal femur where the epiphyseal and physeal cartilage are located depends on the extent of the avascular event. The pathogenesis involves a disruption or interruption of the blood supply to the femoral head (Fig. 99B.5). Thrombophilia (enhanced ability to form clots), hypofibrinolysis (decreased clot breakdown), or both may contribute to the pathogenesis of LCP; LCP with thrombophilia secondary to protein C and S deficiency as well as Leiden V mutation has been reported.¹⁶⁻¹⁸

Treatment

Children with mild LCP often do not require intervention but instead can be observed and managed symptomatically with activity restriction and

Fig. 99B.4 Pelvic radiograph and technetium bone scintiscan for an 8-year-old with Legg-Calvé-Perthes disease. (a) The child has early involvement of the right hip, with relatively subtle changes apparent on the radiograph. (b) The bone scintiscan, however, shows complete blood loss in the right femoral head, consistent with osteonecrosis. The left hip shows classic, more advanced stages of Legg-Calvé-Perthes disease (in the revascularization phase), with return of normal blood flow visible on the scintiscan.

Fig. 99B.5 Normal blood supply to the femoral head in a 4-year-old child. A blockage of this blood supply, which is yet not fully understood, leads to Legg-Calvé-Perthes disease.

physical therapy. This low-risk group includes children who maintain good hip motion (at least 30 degrees of abduction) or who are younger than 6 years of age. However, about 60% require mechanical treatment, which is based on the principle of containment of the femoral head within the acetabulum so that, during healing, the head is molded by the acetabulum. Containment is accomplished by bracing or by surgical intervention using an innominate (Salter) osteotomy, femoral osteotomy, or combination of the two. The role of bisphosphonate therapy in limiting damage by reducing osteoclast and remodeling is still under investigation.¹⁹⁻²¹

Prognosis

Overall prognosis is good, particularly in those younger than 6 years of age with less than half of the epiphysis involved. When more than 50% of the epiphysis is affected and the child is older than 6 years, deformity of the femoral head and metaphyseal damage are more likely, resulting in secondary osteoarthritis in adult life. In more severe disease, the femoral head needs to be covered by the acetabulum to act as a mold for the reossifying of the epiphysis. Age determinations show chronologic age to exceed pelvis bone age and hand-wrist bone age in individuals of both sexes with LCP.²²

Long-term follow-up

A review of 20- to 40-year follow-up studies found that 70% to 90% of patients are active and pain free, regardless of treatment.²³ Growth studies in children followed longitudinally show that affected children are slightly shorter at birth and that they remain shorter over the entire growth period. The femoral head and neck deformity can lead to a “functional retroversion,” causing an externally rotated gait.²⁴

Slipped capital femoral epiphyses

Slipped capital femoral epiphyses (SCFE) is most likely to occur in preteen and early teenaged boys; its overall incidence in the general population is 0.7 to 3.4 per 100,000.^{25,26} Boys are affected at least two to five times more frequently than girls. Peak age at onset is 11.5 years in girls and 13 years in boys.²⁷ Acute SCFE occurs up to 10% to 15% of the time.²⁸ In SCFE, the term *acute* refers to the interval between the onset of pain and presentation to the practitioner (less than 3 weeks), whereas the term *unstable*, as it applies to SCFE, refers to lack of ability of the child to bear weight even with the use of assistive devices such as crutches. Prognosis appears more closely related to whether SCFE is stable or unstable than whether it acute or chronic. In SCFE the slip occurs at the weakest part of the physal plate and results in displacement of the head from the metaphysis. Risk factors for SCFE include obesity, hypothyroidism, and hypoparathyroidism, and perhaps treatment with growth hormone.

Clinical findings

Patients may have no pain at presentation; patients with pain may have had subclinical symptoms such as mild pain or limp for 1 to 3 months. The slip itself usually occurs during the preadolescent growth spurt and is more common in obese children. Up to 25% to 40% of children have bilateral slips, and up to half of children with bilateral slips are asymptomatic for the slip on the side without pain. SCFE should be in the differential diagnosis for hip, thigh, or knee pain in children aged 10 to 15. In unstable SCFE the child most often has severe pain of acute onset comparable to that of a displaced femoral neck fracture.²⁸ A history of mild trauma is frequently present.²⁸ The prognosis is guarded in cases of an unstable slip because a

proportion of children with unstable SCFE go on to develop avascular necrosis of the femoral head.

Imaging

In acute SCFE an anteroposterior radiograph of the pelvis confirms the finding of an abrupt displacement of the epiphysis on the metaphysis. If the acute slip occurs in the setting of a chronic clinically unnoticed slip, then metaphyseal remodeling will be seen along the superior and anterior femoral neck.²⁸ A cross-table lateral view of the hip but not a lateral view in frog-legged position (which could exacerbate the slip) may help assess the presence of anterior physeal separation, a risk factor for avascular necrosis; a cross-table frog-legged view of the contralateral hip should also be obtained.²⁸

Treatment

There is controversy regarding operative treatment of acute SCFE with regard to timing of surgery, method (internal fixation with one or two screws), bone graft epiphysiodesis, reduction of the hip, decompression of the hip joint, and the role of femoral osteotomy; however, a recent meta-analysis concluded that, for stable SCFE, fixation with a single screw without surgical dislocation is superior.²⁹ In contrast, unstable SCFE requires reduction, decompression, and internal fixation. Controversy also exists about whether there is a role for prophylactic pinning of the contralateral hip. Zoledronic acid increases bone density and reduces bone turnover markers in LCP and SCFE but has not yet become standard of care in treating these disorders; adverse effects of zoledronic acid therapy were similar to those reported in adults.^{20,30} Currently there is no effective treatment for traumatic femoral head necrosis in adolescents, although some have suggested that vascularized fibular grafting could be helpful.

Idiopathic chondrolysis

Idiopathic chondrolysis is an uncommon disease in which there is progressive necrosis of hyaline cartilage of both the femoral head and the acetabulum.³¹ Occurring predominantly in teenaged girls, idiopathic chondrolysis is associated with severe pain, stiffness, and an abnormal gait and leads to premature osteoarthritis of the hip. Bilateral disease has been reported.³² Chondrolysis can also occur in association with other conditions, including SCFE, pin perforation during treatment for SCFE, immobilization, hip tumors, traumatic subluxation, intraarticular leak of bone cement, Stickler syndrome, psoriatic arthritis, and septic arthritis.

Imaging

Radiographically, concentric narrowing of the articular space to less than 3 mm (normal range, 3.5 to 7.0 mm) is considered to be diagnostic, and the physeal injury can be associated with decreased width of the femoral neck and head and shortening of the femur. Maximal narrowing appears to develop during the first year, followed by an increase in joint space and motion over the first few years, but then progression occurs with osteoporosis, osteophyte formation, and sometimes protrusio acetabuli. Technetium bone scans show marked periarticular uptake and premature fusion of the epiphysis of the greater trochanter, findings that may precede the abnormalities seen on MRI scans and plain radiographs.

Treatment and prognosis

The prognosis is generally poor, and many patients eventually require hip replacement.

REGIONAL SYNDROMES: KNEE

Patellofemoral dysfunction

Patellofemoral dysfunction, also known as *patellofemoral pain syndrome*, is a common cause of pain in adolescents and in some children; it is described in detail in Chapter 77.

Chondromalacia patellae

Chondromalacia patellae results from softening of the articular cartilage of the patella. The disorder most commonly affects adolescent females, and pain can be reproduced when the patella is tightly apposed to the femoral

condyles, as in standing up from sitting or walking up stairs. Treatment is conservative with rest and physical therapy for quadriceps muscle strengthening.

Bone lesions that mimic mechanical knee disease

Malignant tumors fortunately are rare; osteogenic sarcoma and Ewing tumor may present with pain and/or swelling and may be accompanied by pathologic fracture. Osteoid osteoma is a benign tumor that may affect adolescents (boys more than girls) and usually involves the femur or tibia. Typically pain is most severe at night; the symptoms are thought to be due to local release of prostaglandins and often improve with NSAID therapy. Radiographs are usually diagnostic and show a sharply demarcated radiolucent focus of osteoid tissue surrounded by sclerotic bone. Computed tomography or MRI is sometimes required to detect smaller lesions. Treatment is by surgical removal or curettage. Tumors of bone are described in more detail in Chapter 212.

Osgood-Schlatter disease

Osgood-Schlatter disease is a traction apophysitis seen primarily in boys between the ages of 11 and 17. Physical examination frequently shows tenderness and/or protuberance of the tibial tuberosity. The bone at the age span indicated is thought to be more susceptible to repetitive injury than the patellar tendon, which results in fragmentation of the bone. Disease may be unilateral or bilateral. Treatment consists of icing after activity. NSAIDs can be given to control pain but not at doses that would ease the way for further overuse. Physical therapy to increase flexibility of the thigh muscles accompanied by core strengthening is helpful. Rarely, casting or surgical excision of ossicles is required.

Other knee disorders

Knee extensor tendinitis (jumper's knee) may be seen in young athletes. This disorder, pes anserine bursitis, and iliotibial band syndrome are described in Chapter 77. Performing the Ober test can be quite helpful in diagnosing iliotibial band syndrome. Finally, osteochondritis dissecans is another common cause of knee pain in children and adolescents that typically presents as intermittent knee pain and effusion. The subchondral bone is involved. Treatment is frequently surgical and depends on the size of the lesion. Osteochondritis desiccans, a defect in cartilage, has been treated with débridement, autologous chondrocyte transplantation, and osteochondral allografts; there have been no head-to-head or comparative efficacy studies to support one method over another.

REGIONAL SYNDROMES: FOOT

Talipes equinovarus (*clubfoot*) refers to a condition in which the foot is inverted and supinated and the forefoot is adducted. The affected foot is shorter with less calf muscle bulk than normal, and the condition is frequently bilateral. During plantar flexion the heel rotates inward. *Talipes equinovarus* occurs approximately twice as frequently in male as in female infants, and the overall incidence approaches 1 in 1000 live births. Oligohydramnios, spina bifida, and other congenital disorders may precede this condition. Physical therapy, positional splinting, and surgical correction may be required. *Talipes equinovarus* should be differentiated from *talipes calcaneovalgus*, in which the foot is dorsiflexed and everted. The latter usually self-corrects, but passive foot exercises are sometimes advised. Positional *talipes* from intrauterine compression is common, and if the deformity is mild and foot size is normal, it can be corrected to the neutral position with passive manipulation and exercises.

Skeletal dysplasias and heritable disorders of connective tissue are covered in Section 17.

Classification and epidemiology of juvenile idiopathic arthritis

■ KIRSTEN MINDEN

- Juvenile idiopathic arthritis (JIA) is the most common chronic inflammatory rheumatic disease in the pediatric age period.
- JIA has an annual incidence of approximately 10 per 100,000 children and a prevalence of about 100 per 100,000 in North American and European white populations. For other populations, estimates on occurrence of JIA are almost impossible because of lack of data.
- JIA is a heterogeneous condition and currently classified into seven different categories based on clinical and laboratory features.
- Risk for JIA is attributed to a complex combination of environmental and genetic factors, with a heritable risk of 30%.

CLASSIFICATION OF CHILDHOOD ARTHRITIS

History of childhood arthritis classification

Since the description of the first case series at the end of the 19th century, there have been many names for and attempts at classifying the clinically heterogeneous group of chronic arthritides in children. In the 1970s two classification systems became accepted: in North America, the classification of *juvenile rheumatoid arthritis* (JRA) proposed by the American College of Rheumatology (ACR),¹ and in Europe, the classification of *juvenile chronic arthritis* (JCA) of the European League Against Rheumatism (EULAR).² Both were based on the concept of classification by mode of onset of arthritis and distinguished the same subsets: systemic arthritis, oligoarthritis, and polyarthritis. However, the two classifications did not include identical spectra of disease (Table 100.1), thus impeding comparison of epidemiologic, clinical, serologic, and genetic data.

In an effort to overcome the limitations of the preexisting, somewhat discordant classification systems and to replace them with one unified, internationally accepted classification, in 1993 the International League of Associations for Rheumatology (ILAR) Task Force on the Classification of Childhood Arthritis proposed a new classification using the term *juvenile idiopathic arthritis* (JIA) for all chronic childhood arthritides of unknown cause.^{3,4} According to the ILAR classification, JIA is defined as definite arthritis for a minimum of 6 weeks in a child younger than 16 years. There is no biologic relevance to this age criterion. The term “idiopathic” emphasizes that the cause of the arthritis is unknown. A diagnosis of JIA requires that other known conditions be excluded. This applies, for example, to infection-related arthritides (e.g., Lyme disease). Similarly, arthritis accompanying connective tissue, metabolic, and other genetic disorders is not regarded as JIA.

Role of the International League of Associations for Rheumatology classification

JIA can be diagnosed as early as 6 weeks after the onset of symptoms, whereas allocation to a specific JIA category requires the duration of the disease to be up to 6 months. The ILAR criteria were not developed for clinical decision-making, and therefore their use for clinical diagnosis is inappropriate. The ILAR criteria are based on inclusion and exclusion criteria and seek to define groups of patients with a high degree of internal homogeneity without overlap among the six specific categories. The JIA categories (Table 100.2) are distinguished on the basis of clinical features over the first 6 months of disease, especially the number of affected joints, but also the presence of extraarticular manifestations and rheumatoid factor

(RF). The number “4” as the criterion for assignment to oligoarthritis or polyarthritis is an arbitrary value; however, in an evaluation study of the ACR criteria, Cassidy and colleagues⁵ showed by cluster analysis that involvement of more than four joints is the most important variable associated with outcome in polyarthritis.

A number of “descriptors” have been proposed to gather further information about the pattern of these diseases (e.g., age at onset, antinuclear antibody [ANA] positivity, chronic or acute uveitis), but they are not part of the JIA classification.

Many papers have acknowledged that the ILAR classification distinguishes immunogenetically distinct groups of patients, with variations in regard to the underlying pathogenesis, clinical phenotypes, treatment responses, and disease outcomes.^{6,7} For example, systemic-onset JIA (soJIA) and enthesitis-related arthritis (ERA) are acquired autoinflammatory diseases, whereas other JIA categories are a consequence of a disturbed balance between proinflammatory effector cells and antiinflammatory regulatory cells.^{8,9}

Even though the ILAR classification yields greater clarity and homogeneity than previous classifications do, overlap between and heterogeneity within categories of JIA remain. Overlap exists, among others, between the categories of RF-negative polyarthritis and oligoarthritis; patients with early-onset polyarthritis and oligoarthritis share common clinical and genetic features.¹⁰ This is supported in a study by Ravelli and colleagues¹¹ in which it was demonstrated that ANA-positive patients have similar characteristics but are classified into different JIA categories. On the other hand, heterogeneity within one category has been shown in soJIA,¹² RF-negative polyarthritis,¹⁰ and psoriatic arthritis.¹³ For example, two subtypes of psoriatic arthritis have been recognized. One is similar to early-onset oligoarticular and polyarticular JIA; the other shares features of ERA.

Classification of juvenile-onset spondyloarthritis

The family of juvenile-onset spondyloarthritis (SpAs), which includes juvenile ankylosing spondylitis, reactive arthritis, subsets of psoriatic arthritis, enteropathic arthritis, and undifferentiated juvenile SpA, is not completely encompassed under the term JIA. Diseases included in the juvenile SpA group exhibit overlapping clinical features, such as asymmetric involvement of large joints in the lower extremities, enthesopathy, HLA-B27 positivity, and a family history of this group of diseases. Most children with such features, especially those with isolated forms of arthritis, the seronegative enthesopathy and arthropathy syndrome, and juvenile ankylosing spondylitis, are classified as having ERA in the ILAR approach to classification. Patients with juvenile psoriatic arthritis are considered to have a distinct entity. This is in contrast to the traditional concept of SpA behind the European Spondylarthropathy Study Group (ESSG) classification and the Assessment of SpondyloArthritis international Society (ASAS) axial and peripheral SpA criteria.^{14,15} Both the ERA (ILAR) and the ESSG criteria may properly classify children with SpA. The ERA criteria, however, correspond better to the clinical picture of juvenile-onset SpA because the relevance of enthesopathy in the whole group is much greater than that of inflammatory back pain. The latter is the major diagnostic criterion, besides synovitis, according to the ESSG but is an infrequent event in children with recent-onset disease. Whether the ASAS criteria for axial and peripheral SpA have any role in the classification of children with SpA remains to be determined.¹⁶

Validity of the International League of Associations for Rheumatology criteria

The proposed ILAR classification has been evaluated in more than 15 studies, the majority of which compared the Durban criteria³ with other published classification sets. In these studies, which included almost 3500

TABLE 100.1

Classifications of childhood arthritis

Classification according to	ACR	EULAR	ILAR
Term	Juvenile rheumatoid arthritis (JRA)	Juvenile chronic arthritis (JCA)	Juvenile idiopathic arthritis (JIA)
Age at onset of arthritis	<16 yr	<16 yr	<16 yr
Duration of arthritis	≥6 wk	≥3 mo	≥6 wk
Types of onset	3	3	6 (2 oligoarthritis course subtypes)
Exclusion	Juvenile ankylosing spondylitis, juvenile psoriatic arthritis, Reiter syndrome	Rheumatoid factor–positive polyarthritis	Reactive arthritis

ACR, American College of Rheumatology; EULAR, European League Against Rheumatism; ILAR, International League of Associations for Rheumatology.

children, performance of the ILAR classification has not been analyzed adequately, however. The reliability and precision of the criteria have not been tested, and their feasibility has been rated as relatively low. Berntson and colleagues¹⁷ reported on the difficulties of fulfilling the specified exclusion criteria in clinical work. Face validity of the ILAR classification was, however, affirmed. The ILAR classification is, like its predecessors, based on published literature and expert opinions. The criteria have not been tested against non–rheumatic disease control groups or other rheumatic disease control groups; thus its sensitivity and specificity are unknown.

Nevertheless, the ILAR classification constitutes the currently agreed-on international system of definitions for chronic childhood arthritides of unknown etiology. The proposed classification has restrictions intrinsic to any classification founded on clinical criteria, but it will probably be modified as progress is made in understanding the pathophysiology and phenotypic expression of JIA. Genome-wide technologies for measurement of both DNA and RNA, the increasing availability of validated disease-specific biomarkers, and the development of novel analytic strategies hold promise for providing a biologic basis for classification and a new clinical-immunopathologic classification of childhood arthritis.

DESCRIPTIVE EPIDEMIOLOGY

Published data on occurrence, clinical phenotypes, risk factors, and the natural course of chronic childhood arthritis vary and are difficult to compare and interpret because of the heterogeneity of the disease, differences in the classification criteria used for definition and inclusion, and differences in source populations and case ascertainment.

Incidence and prevalence

JIA is the most common chronic inflammatory rheumatic disease experienced in childhood. Calculation of the incidence and prevalence of JIA incurs three methodologic problems:

1. JIA is a diagnosis of exclusion that is identified clinically without specific diagnostic tests.
2. Because of its low incidence, large sample sizes are needed to provide statistically precise estimates.
3. Non–community-based studies are likely to underestimate the true incidence and prevalence of JIA because of underdiagnosis.

JIA occurs worldwide, but the occurrence of JIA has hitherto been estimated only in European populations (Table 100.3).¹⁸⁻⁴⁹ The incidence is reported to be 3 to 23 per 100,000 children younger than 16 years, and the prevalence is reported to be 16 to 140 per 100,000. These rates were obtained from practitioner-based studies. Oen and Chang⁵⁰ demonstrated that in contrast to the approach of case ascertainment, the kind of classification criteria applied has only relatively little influence on the estimated frequency of childhood-onset arthritis. Therefore, studies on the incidence and prevalence of JRA or JCA according to the ACR or EULAR criteria, respectively, can provide a useful overview of the relative frequency of childhood arthritis in different populations. Restricting consideration to studies published since

TABLE 100.2

Current International League of Associations for Rheumatology classification of juvenile idiopathic arthritis

Category	Definition	Exclusions
Systemic arthritis	Arthritis with or preceded by daily fever of at least a 2-wk duration that is documented to be quotidian for at least 3 days and accompanied by one or more of the following: Evanescent, nonfixed erythematous rash Generalized lymph node enlargement Hepatomegaly and/or splenomegaly Serositis	a, b, c, d
Oligoarthritis	Arthritis affecting 1-4 joints during the first 6 mo of disease	a, b, c, d, e
Persistent	Arthritis affecting no more than 4 joints throughout the course of disease	
Extended	Arthritis affecting a total of more than 4 joints after the first 6 mo of disease	
Polyarthritis (RF negative)	Arthritis affecting more than 4 joints during the first 6 mo of disease; tests for RF are negative	a, b, c, d, e
Polyarthritis (RF positive)	Arthritis affecting more than 4 joints during the first 6 mo of disease; tests for RF are positive (on at least 2 occasions more than 3 mo apart)	a, b, c, e
Psoriatic arthritis	Arthritis and psoriasis or arthritis and at least two of the following: Dactylitis Nail abnormalities (pitting or onycholysis) Psoriasis in a first-degree relative	b, c, d, e
Enthesitis-related arthritis	Arthritis and enthesitis or arthritis or enthesitis with at least two of the following: Presence of or a history of sacroiliac joint tenderness and/or inflammatory lumbosacral pain Presence of HLA-B27 Onset of arthritis in a male older than 6 yr Acute (symptomatic) anterior uveitis History of ankylosing spondylitis, enthesitis-related arthritis, sacroiliitis with inflammatory bowel disease, Reiter syndrome, or acute anterior uveitis in a first-degree relative	a, d, e
Other arthritis	Arthritis that fulfills the criteria in no category or in two or more of the above categories	

a, Psoriasis or a history of psoriasis in the patient or a first-degree relative.

b, Arthritis in an HLA-B27–positive male beginning after the sixth birthday.

c, Ankylosing spondylitis, enthesitis-related arthritis, sacroiliitis with inflammatory bowel disease, Reiter syndrome, or acute anterior uveitis or a history of one of these disorders in a first-degree relative.

d, Presence of IgM RF on at least two occasions at least 3 months apart.

e, Presence of systemic juvenile idiopathic arthritis.

Data from Petty RE, Southwood TR, Manners P, et al. International League of Associations for Rheumatology classification of juvenile idiopathic arthritis: second revision, Edmonton, 2001.

J Rheumatol 2004;31:390-2.

1990, including contemporary studies of JIA frequency, annual incidence rates of chronic childhood arthritis vary from 0.8 to 23 per 100,000, and prevalence rates range from 15 to 400 per 100,000 worldwide (see Table 100.3). Population surveys (with case verification by specialists) yielded the highest prevalence values, between 200 to 400 cases per 100,000, thus pointing to a significant number of children with undiagnosed JIA in a community.

Geographic and ethnic variation

Most studies on JIA frequency are from North America and Europe (see Table 100.3). In the most heavily populated areas of the world, epidemiologic data on JIA are scarce. The studies available from different geographic regions are difficult to compare, but it seems that in North America and Europe, the overall prevalence of JIA is higher than in Asia. The prevalence rate of 0.83 per 100,000 children in Japan is among the lowest documented.⁴⁵

ACR, American College of Rheumatology; EULAR, European League Against Rheumatism; ILAR, International League of Associations for Rheumatology.

Variation in occurrence of JIA has also been observed in populations of different ethnic origin from the same region. In a multiethnic cohort from Toronto, Canada, consisting of more than 800 children and adolescents, European descent was significantly associated with an increased risk for the development of JIA.⁵¹ In contrast, children with Afro-Caribbean, Asian, or Indian ethnic background were less commonly affected by JIA. Lower frequencies of childhood arthritis have also been reported in children of Japanese, Filipino, or Samoan origin than in white children living in Hawaii.⁵²

In Europe, there is a tendency toward a falling north-to-south gradient in the incidence of JIA, with the highest incidence rate registered in northern

Norway (23 per 100,000) and the lowest rate in France (3 per 100,000). There is evidence of a relationship between the latitudinal gradient and occurrence of other autoimmune diseases (e.g., pediatric Crohn disease, multiple sclerosis). The role of latitude (or vitamin D status) with regard to the occurrence of JIA has not been studied adequately.⁵³

Time trends

It is uncertain whether the occurrence of JIA is increasing. Some studies investigating trends recorded a doubling or tripling of the incidence of JIA in observation periods ranging from 3 to 17 years.^{22,25,35}

Fig. 100.1 Age at onset of selected categories of juvenile idiopathic arthritis (JIA) and the entire JIA group in a European population. Data were derived from 5994 patients with JIA recorded in the German pediatric rheumatologic database in 2011. ERA, enthesitis-related arthritis; OA, oligoarthritis; RF- PA, rheumatoid factor-negative polyarthritis; RF+ PA, rheumatoid factor-positive polyarthritis.

In addition, temporal variability in the incidence of JIA has been observed in several studies, thus supporting a possible environmental etiopathogenesis of the disease.⁵⁴

Descriptive epidemiology of the different disease categories

The picture of JIA differs around the world, which suggests true differences in disease manifestations because of immunogenetic or environmental factors or a combination of both.

In white populations from North America and Europe, oligoarthritis constitutes at least half of all incident JIA cases⁵⁵⁻⁵⁷; progression to a polyarticular disease course, labeled as extended oligoarthritis, has been described in a third of cases with oligoarthritis.⁵⁵ Approximately 20% of children with newly diagnosed JIA have polyarticular disease, 10% have ERA, and less than 10% have psoriatic arthritis and soJIA. RF-positive polyarthritis is the rarest JIA category and accounts for less than 5% of cases.⁵⁵⁻⁵⁷

Overall, more girls than boys are affected by JIA, but the sex distribution varies with the JIA category, with a striking female preponderance in oligoarticular and polyarticular onset (girl-to-boy ratio of approximately 3:1), an even distribution of sexes with soJIA, and a male preponderance (male-to-female ratio of 2:1 to 3:1) in ERA.

The different JIA categories have characteristic distributions of age at onset. Oligoarthritis is typically a disease of young children, although onset before 6 months of age is highly unusual. The peak age at onset of oligoarthritis and RF-negative polyarthritis is 2 to 3 years, whereas ERA and RF-positive polyarthritis occur predominantly in children older than 8 years (Fig. 100.1). In general, two major peaks in JIA onset have been observed: at 2 to 3 years and between the ages of 11 and 12 years.

ANAs (for the most part of unknown specificity) are the most frequently detected autoantibodies in JIA (in 40% to 50% of cases).^{51,55,57} They are most commonly seen in patients with oligoarthritis.^{51,55} IgM RFs are rarely found in JIA (<5%) and, by definition, are found only in those with RF-positive polyarthritis or other arthritis.

Extraarticular features differ among the various JIA categories. Systemic manifestations such as fever characterize soJIA, whereas enthesitis is a distinguishing feature of enthesitis-related arthritis. Dactylitis is most commonly seen with juvenile psoriatic arthritis. Uveitis can be observed most frequently in patients with oligoarthritis of the extended course type (cumulative incidence of 25% to 30%), followed by persistent oligoarthritis (16% to 18%) and RF-negative polyarthritis (4% to 14%) or psoriatic arthritis (10% to 12%).^{58,59} Several studies have shown that ANA positivity, age younger than 6 years at onset of JIA, and subtype of JIA are independent

risk factors for uveitis. Uveitis develops in about 90% of cases within the first 4 years of JIA. It is manifested mainly as anterior uveitis but is usually asymptomatic in the most affected JIA subgroups.

In non-European populations, the picture of JIA is different. Oligoarthritis is reported to be relatively uncommon. Its relative rarity has been documented in reports from the Indian subcontinent⁶⁰; Japan, Taiwan, and Thailand⁶¹; and South Africa.⁶² In contrast, polyarticular JIA, ERA, or both have been demonstrated to be more common in Asia, Africa, and Canadian aboriginal groups.⁶² In addition, several studies found a lower frequency of ANA (in particular in oligoarthritis), a lower frequency of uveitis, older age at onset, and no female preponderance in JIA patients from these populations in comparison to European populations.^{60,61} A significant difference in the distribution of JIA subtypes and JIA features among different ethnic groups was confirmed by Saurenmann and colleagues⁵¹ in their cohort study. They demonstrated an underrepresentation of oligoarticular JIA in patients of Asian, Afro-Caribbean, and North American origin. On the other hand, overrepresentation of polyarticular JIA was observed in children of Afro-Caribbean and native North American origin. In particular, the prevalence of RF-positive polyarthritis (16% and 20%, respectively) was higher than in children of European descent (2%).

Risk factors

Evidence suggests that JIA develops as an untoward consequence of interactions between genetic susceptibility and environmental risk factors in a manner that is incompletely understood.

Genetic factors

Familial risk

Compelling evidence for a genetic component in childhood arthropathies has been derived from twin, family, and association studies. Twin studies have shown a concordance rate of 25% to 40% in monozygotic twins for a disease with a population prevalence of 0.1%, thus implying a relative risk of 250 to 400 for a monozygotic twin of a JIA proband. The sibling recurrence risk (λ_s) was estimated to be 12 to 30, and the relative risk for JIA in first cousins of probands with JIA was calculated to be 6.⁶³ Affected sibling pairs are concordant for clinical phenotype, age at onset, and human leukocyte antigen (HLA) haplotypes, which strengthens the evidence that genetic factors play an important role not only in determining susceptibility to JIA but also in the expression of JIA.⁶⁴

Role of HLA

All JIA subsets are complex genetic traits because they lack single-gene, mendelian patterns of inheritance. Genetic variation within the HLA region defines the strongest known genetic risk factor for JIA. Both HLA class I and class II haplotypes, which are associated with JIA, are largely distinct from those in adults with rheumatoid arthritis (RA) and differ among JIA categories. The shared epitope (consisting of selected HLA-DRB1*01/*04 alleles) is associated only with RF-positive polyarticular JIA,⁶⁵ a finding supporting the fact that this JIA subtype is the juvenile equivalent of adult RA. In contrast, HLA-DRB1*04 and HLA-DRB1*07 are protective of the most common JIA subtypes.¹⁰ Interestingly, there is an apparent lack of association between soJIA and HLA.

The most consistent HLA associations have been found for oligoarthritis and include at least three interacting major histocompatibility complex (MHC) components: one class I HLA, a second from DR/DQ, and a third from DP. There are three oligoarthritis-predisposing haplotypes from the DR/DQ loci: DRB1*0801;DQA1*0400;DQB1*0402, DRB1*1103/04;DQA1*0500;DQB1*0301, and DRB1*1301;DQA1*0103;DQB1*0603; all show very strong effects (odds ratios [ORs] of 7.7, 4.8, and 2.3, respectively). Hollenbach and colleagues¹⁰ found that the effects are attributable to DRB1, with no evidence of a role for DQA1 or DQB1. The presence of two predisposing DRB1 alleles significantly increases risk for disease, with ORs ranging from 13 to 23 relative to only a single predisposing DRB1 allele. The DRB1*0801 haplotype is associated with disease regardless of age at onset, whereas the remaining predisposing DRB1 alleles show significant associations only with early-onset disease. Therefore, the very strong effect by two copies of predisposing DRB1 alleles may be related to an age-at-onset effect of the non-DRB1*0801 allele.

HLA variants, however, explain just part of the genetic burden of JIA. It has been estimated that the HLA-DR region accounts for only about 17% of the genetic risk for JIA, which suggests that other variants within and outside the MHC play a role in susceptibility. A recent genome-wide association study estimated that 30% of JIA risk is attributed to common genetic variation and that the extended MHC region accounts for approximately a fourth of the heritable risk.⁶⁶

Role of non-HLA genes

The non-HLA genetic component of JIA appears to be mediated by multiple low-risk polymorphisms. In the past few years, researchers have identified numerous non-HLA risk alleles for JIA through association using both genome-wide and candidate gene approaches. For example, variants at the PTPN22, STAT4, TNF- α , TNFAIP3, MIF, WISP3, SLC11A1 (formerly NRAMP1), and IL-2Ra loci have been shown to be associated with JIA by several groups. Most of these genes/loci confer only modest ORs of about 1.5 and are not unique to JIA but have also been associated with various other autoimmune disorders. It is therefore not surprising that autoimmune diseases cluster in JIA patients, as well as in families. An increased prevalence of other autoimmune disorders, such as autoimmune thyroid disease, diabetes mellitus, or celiac disease, has been found in patients with JIA, with a history of autoimmunity having been demonstrated in 12.6% of first- and second-degree relatives of JIA patients as opposed to 4% of the control population.⁶⁷ A higher prevalence of autoimmunity in maternal versus paternal relatives of children with JIA has been found. Moreover, a significantly higher prevalence of autoimmune diseases has been demonstrated in maternal relatives of JIA cases than in relatives of controls, which suggests a maternal parent-of-origin effect in JIA.

Environmental factors

When compared with identification of genetic risk factors for JIA, research to identify environmental factors has received less attention.

Infectious agents

Seasonal variation in the incidence of JIA (in particular, soJIA) and changes in the incidence of JIA in general over time have been observed. This led to the hypothesis that seasonal differences might reflect differences in the risk for exposure to infectious agents.^{53,54} Oen and coworkers³⁹ correlated yearly incidence trends in Manitoba, Canada, with the occurrence of *Mycoplasma pneumoniae* infection. Other support for the role of infectious agents includes an increase in the incidence of soJIA correlated with enteroviral infections.

A possible link between rubella virus, Epstein-Barr virus (EBV), and parvovirus B19 infection and JIA has been assessed by comparing seropositivity for antiviral antibodies and the presence of viral DNA in patients with JIA and controls, but the studies provided contradictory results.⁵⁵ The study by Massa and colleagues,⁶⁸ however, indicated a possible interaction between genes and infectious agents in determining disease risk. The authors identified sequence homologies between EBV proteins and HLA alleles associated with oligoarticular JIA. They observed a different response of cytotoxic T-cell lines from patients and controls to class II self-HLA-derived peptides homologous to EBV-derived peptides.

In addition, a few studies have pointed to a link between exposure to infections in early life and later disease risk. Pritchard and colleagues⁶⁹ noted an association between intrauterine or neonatal exposure to influenza A and the much later development of polyarticular JCA. A Swedish nationwide register-based case-control study demonstrated an increased risk for later-onset JIA in children hospitalized for any infection during the first year of life (OR, 1.9).⁷⁰

Proxy measures of early-life microbial exposure, such as exposure to pets or animals during the first year of life, living in a rural area or on a farm, birth order, and sibship size, were also used to examine the role of early-life infections or hygiene with regard to risk for the development of JIA. A national Danish cohort study of incident JCA cases found an eight times higher risk for arthritis in an only child living in an apartment with high-income parents than in a child with siblings living on a farm with low-income parents.⁷¹ Other studies could not confirm these findings.⁷²

Stress and psychological factors

Major life events and chronic minor stress have been shown to be risk factors in the pathogenesis of JIA in some studies. Stressful life events were reported in up to a third of JIA patients within a year before disease onset and more often in JIA patients than in controls. In the study by Henoch and associates,⁷³ for example, children whose parents were unmarried as a result of divorce, separation, or death accounted for 28.4% of the JIA population as opposed to 10.6% of the controls. The rate of adoption was more than three times higher in patients than in controls.

Air pollution

Several studies have found that inhalation of airborne substances (e.g., cigarette smoke, particulate matter) can increase the risk for autoimmune diseases.⁷⁴ A Finnish birth cohort study demonstrated an association between fetal exposure to tobacco smoke products and risk for development of

chronic inflammatory polyarthropathies, especially JRA, in the first 7 years of life. Risk for JRA was threefold higher in girls whose mothers had smoked more than 10 cigarettes per day in pregnancy than in girls of nonsmoking mothers.⁷⁵ Another study, however, could not confirm an association between maternal smoking and risk for JIA.⁷⁰

Nutrition

The role of breastfeeding in risk for JIA was assessed in a few studies. Their results, though generally inconsistent, suggest a relationship between breastfeeding and disease risk. One study of infant feeding patterns concluded that children who were breastfed had a lower incidence of JRA (OR, 0.31) than did those who were fed cow's milk. Two other studies could not confirm this but found a difference in the duration of breastfeeding between JRA subtypes.

Summary

Altogether, conflicting data exist regarding each environmental factor that has been investigated, and no final conclusions on environmental risk factors for JIA can be drawn thus far. The scarce data available support the hypothesis that environmental exposures early in life, which might induce changes in functional development, are important in the etiology of JIA.

Course and prognosis

Mortality

The prognosis of patients with JIA has improved considerably in recent decades. Mortality rates in children with chronic arthritis were 4% to 7% in the 1970s, which represented a 10-fold increase over the general population. Survival has improved such that in 2010, Hashkes⁷⁶ reported a mortality rate in children with JIA not significantly different from that in the general population (standardized mortality ratio of 0.57). However, JIA patients are at increased risk for mortality in their adult years. Two population-based studies demonstrated that young adults with childhood-onset arthritis have a roughly fourfold higher overall mortality than the general population does.⁷⁷ Knowledge about specific causes of death in patients with JIA is very limited. In the 1970s the major causes of death were renal failure (in half the cases secondary to amyloidosis) and infections. Currently, macrophage activation syndrome is the leading cause of JIA-related mortality in childhood. It occurs mainly in soJIA, which still accounts for two thirds of the mortality seen in those with JIA. To what extent cardiovascular diseases, infections, or even hematopoietic malignancies contribute to the increase in mortality, especially later in life, has been unidentified. Preliminary data point to an increased rate (threefold higher) of incident malignancy (particularly of the lymphoproliferative type) in patients with JIA that cannot be explained by the introduction of biologic therapies.⁷⁸

Outcome

Outcome studies published since 2000 show that JIA frequently continues into adulthood. Most remissions occur in the first 5 years after disease onset. After more than 10 years of disease duration, 40% to 60% of the patients still have active arthritis. The probability of remission varies significantly with the type of disease onset, being best for oligoarticular JIA, at approximately 50%, and worst for polyarticular JIA, in which it approaches 15%. After a duration of disease of 15 years, more than a third of young people with JIA have experienced significant articular or extraarticular damage (or both), such as radiographic joint changes, growth disturbances, osteopenia, osteoporosis, and visual loss.⁷⁷

Despite the long-term persistence of disease activity or the need for drug treatment in most patients, a pronounced improvement in functional outcome has been documented. In the 1970s, the percentage of patients with serious functional disability (American Rheumatism Association functional classes III and IV) ranged from 17% to 22%, whereas a lower percentage of patients with serious functional disability ranging from 2% to 10% has been observed since the 1990s. According to the results from a more sensitive measure of function, the Health Assessment Questionnaire (HAQ), approximately 40% of young adults with JIA are somewhat limited in their functional capacity (HAQ > 0) and 10% are in need of assistance or aids to manage their daily routines.⁷⁷ There is also a negative effect of JIA on general health status and quality of life, and despite better than average educational achievements, patients with JIA have lower employment rates.

Several indicators of a poor JIA outcome have been identified, including greater severity or extension of arthritis at onset, symmetric disease, early wrist or hip involvement, the presence of RF, and persistent active disease. Most interesting so far has been prediction of prognosis based on early treatment response, with outcomes at 3 to 12 months predicting response at later points in time.

Clinical features of juvenile idiopathic arthritis

■ ELLEN NORDAL ■ MARITE RYGG ■ ANDERS FASTH

- Juvenile idiopathic arthritis (JIA) is defined as arthritis of unknown etiology that begins before the 16th birthday and persists for at least 6 weeks, provided other known conditions are excluded.
- JIA is the most commonly diagnosed rheumatic disease in children and an important cause of disability and acquired blindness.
- The clinical features of JIA are heterogeneous. When the International League of Associations for Rheumatology criteria are used for classification, eight clinical categories can be identified. Different clinical pictures at onset and during the course of the disease can provide guidance for treatment and prediction of outcome.

INTRODUCTION

Juvenile idiopathic arthritis (JIA) is the most commonly diagnosed rheumatic disease in children and can be an important cause of disability. The disorder is nearly as common as diabetes in children and four times more common than childhood leukemia.^{1,2} The classification of juvenile arthritis has been a challenge because of the heterogeneity of the disease. The International League of Associations for Rheumatology (ILAR) classification³ aims at defining biologically more homogeneous groups than the formerly used classification systems to enhance scientific and clinical communication globally. However, the ILAR criteria represent a change not only in terminology but also in definition of the categories. Because many studies have used the American College of Rheumatology or European League Against Rheumatism criteria, it is still important to be aware of these differences in definitions.^{4,5} The classification and descriptive epidemiology of JIA are reviewed in Chapter 100.

There is no single diagnostic test available for JIA. The diagnosis is based on a combination of findings from a careful history taking, a thorough physical examination, and unspecific laboratory tests. Many disorders can cause arthralgia and a limp (Tables 101.1 and 101.2). The rest of this chapter describes symptoms and signs that can aid in reaching a correct diagnosis and categorization and allow evidence-based predictions on the course and outcome of JIA.

GENERAL CLINICAL FEATURES

Arthritis is the main clinical feature in JIA and is defined as swelling within a joint or limitation in range of joint movement with joint pain or tenderness that persists for at least 6 weeks, is observed by a physician, and is not due to primary mechanical disorders or other identifiable causes (Table 101.3).³

Children with chronic arthritis most commonly have joint swelling and gait disturbance. Joint swelling in children is not always easy to notice, complaints are diffuse, and more than one joint may be involved. A thorough evaluation of all joints is therefore warranted. Morning stiffness is often intense, and nonspecific symptoms such as tiredness, mood changes, loss of appetite, and low-grade fever may be seen. Although musculoskeletal pain is the most common reason for referral to pediatric rheumatology clinics, isolated musculoskeletal pain is rarely a presenting complaint in children with chronic arthritis.⁶ Pain is, on the other hand, an important component in the management of JIA (see later).

LABORATORY INVESTIGATIONS

There is no single laboratory test that differentiates JIA from other diseases. The main role of laboratory investigations is to exclude other diseases such as leukemia or infectious arthritis. Antinuclear antibodies (ANAs), rheumatoid factor (RF), and HLA-B27 all lack any discriminatory ability to identify children with JIA. They are mainly useful in further categorization and the prediction of outcome.

Erythrocyte sedimentation rate (ESR), C-reactive protein (CRP) level, and thrombocyte count are useful tests to differentiate children with JIA from children with noninflammatory disorders. However, a normal ESR and/or CRP level cannot be used to rule out JIA when convincing clinical signs are present, because almost half of children with JIA have normal values at the onset of the disease in a population-based setting.⁷ The ESR and CRP level can be very high in the systemic and polyarticular categories of JIA, and thrombocytosis may be present.

Anemia can occur in all forms of JIA but is more pronounced in the systemic and polyarticular groups. Usually the anemia is secondary to chronic inflammation, as reflected by low serum iron level, low iron-binding capacity, and normal hemosiderin stores. Serum ferritin level may be elevated because it is an acute-phase protein mirroring inflammatory activity and not iron stores. In systemic JIA very high ferritin levels can be found and are a signal of complication with macrophage activation syndrome.⁸ Treatment with corticosteroids and nonsteroidal antiinflammatory drugs may cause intestinal blood loss and secondary iron deficiency, which usually responds to iron supplementation.

Leukocytosis with a neutrophil predominance is seen in children with systemic JIA and is also common in those with polyarticular JIA. Although mild to moderate thrombocytosis is common, thrombocytopenia is not part of JIA and should prompt a workup for systemic lupus erythematosus (SLE) or malignancy, especially leukemia. Serum immunoglobulin levels can be elevated, as can the antistreptococcal titers, even in the absence of a recent streptococcal infection.

ANAs are found in 40% to 85% of cases of early-onset oligoarticular JIA and are associated with chronic uveitis. The specific antinuclear antigen(s) responsible for the ANA positivity in JIA have not been identified. However, there are some indications that antihistones may be associated with JIA and serve as predictors of uveitis.⁹ The disease-specific ANAs that are detected by most enzyme-linked immunosorbent assay-based ANA tests are not associated with JIA or uveitis, and if they are found a workup for juvenile SLE is warranted, especially in teenagers with arthritis.

Immunoglobulin M (IgM) RF and anti-citrullinated protein antibodies (ACPAs) are almost exclusively present in teenagers with polyarticular JIA.¹⁰ Both ANA immunofluorescence and RF IgM may be transiently and non-specifically present in any inflammatory reaction. Two positive test results at least 3 months apart are needed for these markers to be recognized as disease descriptors in JIA.³

HLA-B27 is found in 14% to 42% of JIA patients in different populations.^{11,12} The exact role of HLA-B27 in JIA is not fully understood. It can be found in all JIA categories but is most common in enthesitis-associated arthritis. It is associated with clinical manifestations of enthesitis and sacroiliitis as well as more severe outcome.¹³

At present, research into new biomarkers of disease activity, such as cytokines and MRP8/14, in addition to immunogenetic markers is ongoing, but no test has yet been established as a routine clinical tool to help in diagnosis, categorization, or outcome prediction in JIA.¹⁴⁻¹⁶ Synovial fluid shows white blood cell counts ranging from 600 to 100,000 cells/mm³ (0.6 to 100 × 10⁹/L).

TABLE 101.1
Conditions with arthralgia/arthritis that might be confused with juvenile idiopathic arthritis

Type of condition	Examples
Infections	Bacterial arthritis and osteomyelitis Borreliosis (Lyme disease) Viral and mycoplasmal arthritis Tuberculosis
Postinfectious conditions	Rheumatic fever Poststreptococcal arthritis Postenteritis and other reactive arthritis (<i>Salmonella</i> , <i>Campylobacter</i> , <i>Chlamydia</i>)
Noninflammatory conditions	Hypermobility and Ehlers-Danlos syndrome Growing pains, trauma, patellofemoral and other overuse syndromes Osgood-Schlatter disease and other juvenile osteochondroses Legg-Calvé-Perthes disease Slipped capital femoral epiphysis Foreign body synovitis Other congenital and genetic disorders of supportive tissue
Hematologic disorders	Sickle cell anemia Hemophilia Von Willebrand disease
Systemic inflammatory disorders	Juvenile systemic lupus erythematosus Juvenile dermatomyositis Mixed connective tissue disease Scleroderma Vasculitis (e.g., Henoch-Schönlein purpura, Kawasaki disease, Behçet disease)
Autoinflammatory disorders	Cryopyrin-associated periodic syndrome Familial Mediterranean fever Other monogenic diseases (e.g., mevalonate kinase deficiency [hyperimmunoglobulinemia D], Blau syndrome, tumor necrosis factor receptor–associated periodic syndrome) Chronic recurrent multifocal osteomyelitis Periodic fever, aphthous stomatitis, pharyngitis and adenitis (PFAPA syndrome)
Malignancies	Leukemia Neuroblastoma Localized bone tumors
Pain	Complex regional pain syndrome Pain amplification syndromes and fibromyalgia Nonspecific musculoskeletal pain
Miscellaneous conditions	Primary immunodeficiencies Sarcoidosis

Imaging

Traditionally, radiography was the imaging modality of choice in JIA but could only indirectly describe synovial and soft tissue inflammation. Radiography is not able to detect the presence and degree of inflammation or the precursors of bony destruction for prediction of permanent damage. Newer modalities like ultrasonography and magnetic resonance imaging (MRI) have therefore assumed increasing importance in the diagnostic workup as well as in assessment of inflammatory activity and response to medical treatment. Whether these newer modalities will also prove superior to radiography in assessing damage and predicting outcome remains to be seen. Ossification of cartilage increases with age in children.¹⁷ A major challenge in pediatric rheumatologic imaging is differentiating early signs of permanent bone and cartilage destruction from normal alterations in bone marrow composition, skeletal growth, and maturation.

Early radiographic changes in JIA include soft tissue swelling around affected joints and juxtaarticular osteopenia and periosteal new bone formation (Fig. 101.1), resulting in a widened midportion of the phalanges. In contrast with adult RA, erosions are a late finding because much of the cartilage in growing joints is not calcified, and visualization of erosions is possible only after the cartilage has calcified. Joint space narrowing is an early, but indirect, sign of cartilage destruction. Erosions or joint space narrowing can be found as early as a couple of years from the onset of active arthritis in a child with systemic or polyarticular JIA. Even in severe JIA destroyed cartilage can be replaced with fibrocartilage if the disease becomes quiescent (Fig. 101.2). Growth-arrest lines may result from temporary loss of growth velocity and may be seen around the knee. The sacroiliac joints in young patients are difficult to interpret because of the open epiphysis at the sacroiliac joints in growing children. Radiographic scoring systems specific for JIA have been suggested.^{18,19}

MRI can be an excellent modality for demonstrating the articular cartilage, fluid, and soft tissue structures in the joint. Contrast-enhanced sequences are valuable because they can demonstrate synovitis (Fig. 101.3).²⁰ Dynamic MRI can be used to demonstrate sacroiliitis in children with clinical characteristics consistent with spondyloarthritis.²⁰ An increasing range of MRI techniques with different pulse sequences are presently used to improve the visualization of relevant tissue, but challenges remains in defining and standardizing normal developmental changes in children.¹⁷ No reliable MRI-based scoring system for synovitis in JIA is yet available because the systems published so far have shown high interobserver variability.²¹ MRI is also expensive and time consuming, and general anesthesia is often necessary in young children.

Ultrasonography, which can be done at the bedside, is helpful in visualizing joint effusions, synovitis, and other soft tissue inflammations, including enthesitis, and has the advantage of being easier to perform with no need for general anesthesia.²⁰ It can be used to guide the needle for intraarticular injections, and with power Doppler function it is possible to follow synovial inflammation during the disease course and interventions (Fig. 101.4).²² To assess inflammation and erosion in the developing and maturing skeleton and soft tissue remains a particular challenge in children, and

TABLE 101.2
Common musculoskeletal causes of limp in children other than juvenile idiopathic arthritis

Cause	Age		
	1-4 yr	5-10 yr	11-15 yr
Vascular disorder		Legg-Calvé-Perthes disease, Köhler disease, and similar diseases	Freiberg disease Osteochondritis dissecans
Infection/inflammatory disorder	Septic arthritis Osteomyelitis Diskitis Postinfectious arthritis	<i>Borrelia</i> arthritis	<i>Borrelia</i> arthritis Septic arthritis (tuberculosis, gonococcal infection)
Trauma	Fracture Child abuse		Osgood-Schlatter disease
Malignancy	Leukemia		Osteosarcoma Osteoid osteoma
Anomaly	Hip dysplasia	Diskoid meniscus	Tarsal coalition
Metabolic disorder	Rickets Renal disease		Osteoporosis
Neuromuscular disorder	Cerebral palsy Muscular dystrophy		

TABLE 101.3
Characteristics of the various categories of juvenile idiopathic arthritis

Category	Age at onset	Affected joints	Systemic features	Major complications
Oligoarticular persistent	Early childhood	Large joints, asymmetric (knee, ankle, wrist, elbow, temporomandibular, cervical spine)	No	Chronic uveitis Local growth disturbances
Oligoarticular extended	Early childhood	Same as above, but >4 joints involved after the first 6 months of disease	No	Chronic uveitis Local growth disturbances
Polyarticular RF negative	Throughout childhood	Any, often symmetric, often small joints	Malaise (subfebrile)	Chronic uveitis Local growth disturbances
Polyarticular RF positive	Teenage years	Any, usually symmetric and involving small joints	Malaise (subfebrile)	Local growth disturbances and articular damage
Systemic	Throughout childhood	Any (not necessarily at disease onset)	High fever, rash, polyserositis, marked acute-phase response	Acute: macrophage activation syndrome Chronic: general growth disturbance, amyloidosis
Psoriatic	Late childhood	Spine, lower extremities, distal interphalangeal joints, dactylitis		Psoriasis Local growth disturbances
Enthesitis-related	Late childhood	Spine, sacroiliac, lower extremities, thoracic cage joints	Inflammatory bowel disease	Acute symptomatic uveitis

RF, rheumatoid factor.

Fig. 101.1 Extended oligoarticular juvenile idiopathic arthritis in an 8-year-old. Epiphyseal destruction and undergrowth of the third metacarpophalangeal joint of the left hand are seen, as well as overgrowth of the carpal bones of the right wrist compared with the left wrist. Also note the widened appearance of the third phalanges caused by periosteal new bone formation.

standardizations and definitions used in adult rheumatology are not always suitable.²³

CLINICAL FEATURES OF DIFFERENT CATEGORIES OF JUVENILE IDIOPATHIC ARTHRITIS

Systemic arthritis

Systemic arthritis is the category most often associated with severe short- and long-term morbidity as well as increased mortality. Today it is viewed as a different entity than the other categories of JIA and is considered to belong to the autoinflammatory disorders.⁸ It typically comprises 5% of the total unselected JIA population and is defined by its extraarticular features of fever and rash. Girls and boys are affected equally, and onset can occur throughout childhood. The extraarticular manifestations may precede the articular signs by weeks, months, or even years. The fevers typically rise to more than 39° C daily and return to less than 37° C between fever peaks for at least 2 weeks before this diagnosis can be confirmed. Fever usually occurs daily or twice daily and often appears late in the afternoon or

Fig. 101.2 Hip arthritis in systemic juvenile idiopathic arthritis. (a) Hip joint space narrowing bilaterally. (b) There was recovery of joint space 2 years later (standing view).

evening, returning to normal or below normal in the morning (Fig. 101.5). Classically, the child appears toxic with the fever and can have accompanying shaking chills, but not rigor.

In 90% of cases a characteristic evanescent salmon-colored macular or maculopapular rash (Fig. 101.6) occurs on the trunk and thighs, most commonly when the fever is present. The rash can be brought out by scratching

Fig. 101.3 Magnetic resonance images of a swollen ankle in a 5-year-old boy. In addition to talocrural arthritis, joint fluid and synovitis are also present in the subtalar and the talonavicular joint (arrows). There is bone marrow edema of the talus on the short tau inversion recovery image (a). Fat-suppressed T1 image after administration of intravenous contrast (b) shows tenosynovitis (arrows).

Fig. 101.4 (a) Drawing of the normal thin dorsal recesses of the radiocarpal (rc) and midcarpal (mc) joints, pointing distally. (b) Drawing of hypertrophic thickened synovial recesses of the radiocarpal and midcarpal joints. (c) Dorsal sagittal ultrasonographic scan of a hypoechoic thickened radiocarpal recess, Lun, lunate bone; Cap, capitate bone. (From Laurell L, Court-Payen M, Nielsen S, Zak M, Fasth A. *Ultrasonography and color Doppler in juvenile idiopathic arthritis: diagnosis and follow-up of ultrasound-guided steroid injection in the wrist region. A descriptive interventional study. Pediatr Rheumatol* 2012;10:11. Available at www.ped-rheum.com/content/10/1/11. Accessed April 21, 2012.)

Fig. 101.5 An example of the typical fever curve seen in systemic juvenile idiopathic arthritis (JIA).

Fig. 101.6 The rash of systemic juvenile idiopathic arthritis. Larger lesions are becoming confluent (a). This must be differentiated from erythema marginatum (b), characteristic of the rash seen in rheumatic fever.

of the skin (Köbner phenomenon) or a hot bath and is occasionally pruritic. Generalized lymphadenopathy and hepatosplenomegaly occur in 50% to 75% of patients. The child may complain of abdominal pain secondary to hepatomegaly. Liver enzyme levels may be slightly elevated, although fulminant hepatic failure is rare. Polyserositis is common, with about one third of patients having documented pericarditis (Fig. 101.7). Most pericardial involvement is subclinical. Tamponade and myocarditis rarely occur. Pulmonary disease is equally unusual and manifests as pneumonitis, pleural effusion, or pulmonary fibrosis. Central nervous system involvement with coma and meningitis is very unusual.²⁴

Approximately half of the children with systemic JIA develop polyarthritis within 3 to 12 months of the onset of the fever. The wrists, knees, and ankles are most commonly involved, with the cervical spine, hips, temporomandibular joints, and hands also being affected. Cricoarytenoid arthritis resulting in hoarseness, permanent voice changes, and laryngeal stricture has been reported.²⁵

Macrophage activation syndrome or secondary hemophagocytic lymphohistiocytosis is a serious complication that occurs in about 5% of children with systemic JIA. Macrophage activation syndrome is characterized by the rapid development of fever, rash, and encephalopathy; rapid rise of liver transaminase levels; disseminated intravascular coagulopathy; neutropenia; thrombocytopenia; increased triglyceride levels; low albumin level; and a low ESR associated with hypofibrinogenemia. A coagulopathy is present with an increase in fibrin degradation products and prolonged prothrombin time and partial thromboplastin time. The diagnosis is made clinically and is supported by very high ferritin levels (often more than 10,000 mg/L), soluble transferrin receptor (sCD25), and demonstration of hemophagocytosis in the bone marrow, liver, and/or spleen. Because the mortality has been as high as 50% in some series, prompt treatment with corticosteroids and cyclosporine is necessary and, if there is a poor response, also etoposide or antithymocyte globulin.^{26,27}

Oligoarthritis: persistent and extended

Cases in which fewer than five joints show active disease during the first 6 months of the disease course may be classified into many of the JIA categories depending on additional features. Psoriasis, enthesitis or sacroiliitis, and genetic traits for psoriasis or ankylosing spondylitis are exclusion criteria for oligoarthritis. The disease may instead be categorized as psoriatic arthritis, enthesitis-related arthritis, or undifferentiated arthritis (see later).^{3,28} Most often, however, arthritis in a child with fewer than five actively affected joints fits into the most common category of oligoarticular JIA, which may be further divided into persistent or extended oligoarthritis, according to the number of joints involved after the first 6 months. At least one third of children develop extended oligoarticular disease with five or more joints involved during the disease course.²⁹

The majority of children with oligoarticular JIA are younger than 5 years of age at presentation, with a peak onset between 1 and 3 years of age. Oligoarticular JIA occurs more frequently in girls, with a female-male ratio of 2:1 for the persistent category and 5:1 for the extended category. Commonly, such children are brought to the physician because of a limp⁷;

complaints of pain are infrequent. Typically there are no constitutional signs or symptoms. In the majority of cases laboratory findings are close to normal, with little or no increase in CRP level and ESR and no leukocytosis. If only one joint is involved and the joint is painful and red, a more likely diagnosis is septic arthritis, especially if the child has a fever or there is a marked inflammatory response. The knee is the most commonly affected joint (47%) (Fig. 101.8), followed by the ankle and then either the small joints of the hand or the elbow. Involvement of the temporomandibular joint and cervical spine is also common, whereas involvement of other joints occurs less frequently. Arthritis limited to the hip is extremely rare in this category, and if it is present the diagnosis should be questioned.

The immunofluorescence ANA test yields positive results in 40% to 85% of children with oligoarticular JIA, both persistent and extended, and a positive ANA finding is associated with chronic asymptomatic anterior uveitis. The association with uveitis is particularly strong for girls (younger than 5 years) with ANA-positive arthritis, regardless of number of active joints.⁹

Polyarthritis

Approximately 25% of children with JIA have polyarticular onset with five or more joints involved in the first 6 months of disease. Two categories of polyarthritis are defined depending on the existence of persistent serum IgM RF.

Rheumatoid factor–negative polyarticular juvenile idiopathic arthritis

In RF-negative polyarticular JIA the joints tend to be symmetrically involved, with the knees, wrists, and ankles being most commonly affected. In the hands the metacarpophalangeal and proximal interphalangeal joints are involved, and flexor tenosynovitis is common (Fig. 101.9). The cervical spine is often affected, and occasionally patients have torticollis. Hip and shoulder involvement may occur, but rarely at onset. Systemic features such as fatigue, low-grade fevers, mild hepatosplenomegaly, and anemia may occur.

Rheumatoid factor–positive polyarticular juvenile idiopathic arthritis

Teenagers with early involvement of the small joints, unremitting inflammatory activity, nodules similar to those seen in adult rheumatoid arthritis (RA), and early development of erosions on radiographs are more likely to have IgM RF and ACPAs,¹⁰ disease persistence, and poor outcome. Systemic features are rare, except for fatigue and anemia. The presentation of this category of JIA is very similar to that of seropositive adult RA. Most patients are female and older than age 12 at presentation. Symmetric involvement of the small joints is most typical, including the metacarpophalangeal, proximal interphalangeal, and metatarsophalangeal joints as well as sometimes the distal interphalangeal joints. Large joints tend to be involved only in association with small-joint involvement. Flexor tenosynovitis is common and often results in trigger fingers.

Fig. 101.7 Radiograph of a 3-year-old with systemic juvenile idiopathic arthritis who had pericardial effusion at presentation.

(a) Symmetric involvement of metacarpophalangeal and proximal interphalangeal (PIP) joints typical of polyarticular juvenile idiopathic arthritis (JIA) in a 9-year-old girl. (b) More advanced changes can evolve over time with joint deviations, as in this teenage boy. (c) Asymmetric arthritis with swelling and extension deficit in the fourth PIP joint in a young girl with oligoarticular JIA. (Courtesy Ellen Nordal.)

Psoriatic arthritis

Dactylitis, nail pitting, distal interphalangeal arthritis, and asymmetric RF-negative peripheral arthritis are typical findings in juvenile as well as adult psoriatic arthritis. A significant proportion of children may develop inflammatory back disease, including spondyloarthritis and sacroiliitis. Results of an ANA immunofluorescence test were positive in one third of children fulfilling the ILAR criteria for psoriatic arthritis in one epidemiologic study in Scandinavia.²⁸ Because juvenile psoriatic arthritis is such a heterogeneous category, some have recently also questioned whether psoriasis should define a distinct disease category in JIA.³⁰

Enthesitis-related arthritis

Enthesitis-related arthritis affects boys more than girls and presents most commonly after the age of 9 years.²⁸ Arthritis typically involve the lower extremities, most commonly the knees and ankles, but the hip can also be affected.³¹ Enthesitis, defined by ILAR as “tenderness at the insertion of the tendon, ligament, joint capsule or fascia to bone,”³³ occurs frequently and is commonly seen as plantar fasciitis, Achilles tendinitis, and patellar tendon enthesitis. Enthesitis can be difficult to differentiate from arthritis, especially in a child with back pain. Inflammatory back pain is often seen, defined as “lumbosacral spinal pain at rest with morning stiffness that improves on movement.”³³ Many of these children later develop sacroiliitis and spondyloarthritis (Fig. 101.10).

The enthesitis-related arthritis category in JIA incorporates those conditions traditionally viewed as spondyloarthritis in adults, including juvenile ankylosing spondylitis, the syndrome of seronegative enthesopathy and arthropathy (SEA syndrome), but also arthritis associated with inflammatory bowel disease.³¹

Enthesitis-related arthritis is difficult to diagnose correctly during childhood because some of the features defining the category typically develop over many years of disease, which causes much frustration for the family and physician. The full picture might not be seen until adulthood. Also, this is a category in which pain, especially diffuse back pain, might be the initial symptom bringing the teenager to seek medical advice. The association with HLA-B27 is strong, and those with HLA-B27, a family history of spondyloarthritis, and definite arthritis are more likely to develop a definite spondyloarthritis at follow-up. Iritis, usually acute and symptomatic, occurs in 15% to 25% of children in this group. Another major complication can be severe hip disease, requiring early total hip replacement. In this category, inflammatory bowel disease must be considered if there is a persistent fever associated with the arthritis.

Undifferentiated arthritis

Undifferentiated arthritis is a rather unsatisfactory defined category that results from the goal of the present ILAR classification to form homogeneous categories. Cases are excluded from the other categories either because they fulfill criteria for two or more categories or because an exclusion criterion did not allow them to be put into any of the other categories. In a Scandinavian epidemiologic study using the present ILAR criteria, about 15% of JIA cases could not be classified into any of the other categories.²⁹ Almost

Fig. 101.10 Disease course and joint involvement in enthesitis-related arthritis in a HLA-B27 positive boy.

all of these children had oligoarthritis, extended or persistent, or enthesitis-related arthritis, and the main reason for exclusion was a family history of psoriasis or fulfillment of the criteria for more than one category.

SPECIAL PROBLEMS OF ARTHRITIS IN THE CHILD

Children and adolescents with rheumatic diseases have specific problems that do not pertain to adults. For example, delayed physical development as shown by growth and puberty may occur in all childhood rheumatic diseases and must be carefully monitored. Growth disturbances can be local or general. Osteopenia in the growing child can result in later osteoporosis. The chronic, asymptomatic uveitis that may occur in childhood arthritis is specific to children. Pain and fatigue have different manifestations in children and may severely affect daily life.

Local growth disturbances

Local factors that influence bone growth include cytokines produced as a result of the joint inflammation. The cytokines stimulate osteoblasts to increased epiphyseal growth but also stimulate maturation and closure of

the epiphysis if the condition is very long-standing. Also, muscle spasm, capsular and ligamentous contracture or rupture, destructive synovitis, erosion of articular surfaces, and subluxation of articular surfaces can influence local growth.

Knee

The most frequent site of overgrowth is the inflamed knee. The result is leg-length inequality, with the longer leg on the side of the involved knee, particularly if the disease begins before the age of 3 years (see Fig. 101.8).³² To prevent functional scoliosis shoe lifts can be used to equalize the difference in leg length. Valgus deformity and atrophy of the muscles in the affected thigh might be seen as a complication of long-standing knee arthritis, especially in the youngest children. Occasionally, the local growth disturbance results in early epiphyseal closure, causing a permanently shorter leg on the side of the involved knee (Fig. 101.11).

Ankle

Valgus deformity in the ankle is a common sequela of arthritis in the talocrural, subtalar, or tarsal joints (Fig. 101.12). These changes may be reversible in a growing child if the arthritis responds to treatment. Pain at walking may otherwise limit physical function, although correction of the deformity by orthopedic soles is usually helpful.

Wrist and hand

Another common joint to experience growth abnormalities is the wrist. In contrast to the knee, many growth defects seen radiographically in the wrist

are not observed clinically. The wrist can show increased bone age (see Fig. 101.1) and carpal bone fusion with long-standing involvement. Growth defects are also seen in the ulna, the carpal length, and the fourth and fifth metacarpal bones. Because of epiphyseal undergrowth, the ulna can become shorter than the radius, which results in ulnar migration of the carpal bones, subluxation, and severe deformity. Brachydactyly can occur in the fingers or toes as a result of early epiphyseal closure (see Fig. 101.1). In polyarticular disease, especially if RF positive, radiologic abnormalities of the wrist and hand can already be seen at the time of diagnosis.³³

Hip

Growth abnormalities in the hip include lack of growth of the iliac bone and a coxa valga deformity with widening of the femoral neck and/or premature fusion leading to stunting of the femoral neck.

Cervical spine

The cervical spine can develop growth abnormalities that result in apophyseal joint space narrowing and bony ankylosis (especially C2-C3) (Fig. 101.13). Similar findings are not seen in the lumbar spine, but compression fractures of the thoracic spine occur, particularly in children taking corticosteroids.

Temporomandibular joint

Temporomandibular joint involvement is very common and is often overlooked because young children have difficulties describing symptoms in the area. Thus clinical signs of mandibular dysfunction such as reduced opening of the mouth, TMJ crepitations, and restricted horizontal movements are important to look for. Even a thorough evaluation still might not reveal the early signs of condylar lesions, which can present early, can progress insidiously, and might lead to malocclusion and severely alter the craniofacial profile. Unilateral TMJ disease can result in deviation to the affected side of the jaw on opening the mouth resulting in facial asymmetry due to mandibular hypoplasia (Figs. 101.14 and 101.15). TMJ involvement occurs in all categories of JIA. Regular evaluation of all children with JIA by a pediatric dentist or orthodontist is therefore recommended to enable early detection and intervention.³⁴

General growth disturbance

Generalized growth disturbance has been observed and is related to active disease intensity and duration. During quiescent periods of the disease, height can return to normal in 2 or 3 years if premature closure of the epiphysis has not occurred.

Fig. 101.11 Oligoarticular juvenile idiopathic arthritis with arthritis in the right ankle. (a) A shorter leg length from the knee to the ankle is seen. (b) The right foot is smaller, with underdevelopment of the right forefoot due to disuse.

Fig. 101.12 Valgus deformity in the left ankle due to longstanding arthritis in a 5-year-old girl with juvenile idiopathic arthritis since age 21 months. (Courtesy Marite Rygg.)

Fig. 101.13 Systemic juvenile idiopathic arthritis in a child who had a polyarticular course. Her neck shows apophyseal fusion of C2 to C4 and undergrowth of adjacent vertebrae.

Fig. 101.14 Temporomandibular joint involvement. Note growth failure of lower jaw (a) and malocclusion on the radiograph (b).

The cause of delayed growth is unclear, but it is tightly linked to the level of general inflammation. Studies suggest that severe weight loss or lack of weight gain may also contribute to the lack of growth. Nutritional studies have suggested that decreased caloric intake, increased metabolic needs beyond recommended daily requirements, or lack of essential vitamins can result in decreased weight and growth velocity. Even today with better control of the disease, 5% to 10% of children with JIA are estimated to be growth restricted,^{35,37} mainly patients with unremitting systemic, polyarticular, or extended oligoarticular disease. Corticosteroid therapy also inhibits growth, but usually not skeletal maturation (Fig. 101.16). Growth retardation is likely to occur with corticosteroid dosages higher than 5 mg/m²/day (corresponding to about 0.125 mg/kg/day) for 6 months or longer, but individual tolerance may vary.³⁸

Levels of growth hormone (GH) and insulin-like growth factors 1 and 2 (IGF-1, IGF-2) are usually normal but occasionally reduced. Levels of IGF-1 have been found to be inversely correlated with interleukin-6 levels in systemic disease.³⁹ GH has been given to children with JIA with normal GH levels and has resulted in increased mean height velocity. Response to GH is best when the disease is inactive and no or very low doses of corticosteroids are used.⁴⁰ Careful monitoring of the growth of the child with JIA

Fig. 101.15 Failure of development of the lower jaw 5 years after onset of systemic juvenile idiopathic arthritis. The neck is short and slightly flexed.

is mandatory in the follow-up, and when reduced growth is assessed, it is also important to evaluate the nutritional status of the child.

Osteopenia

Osteopenia, or low bone mass for age, is a well-known complication of JIA. An important determinant of future fracture risk is the attainment of a high peak bone mass, which is completed during adolescence. Peak bone mass is determined by genetic as well as environmental factors, such as nutrition, exercise, and levels of hormones, especially estrogen. In children with JIA, active disease, poor nutrition such as low calcium and vitamin D intake, use of drugs such as corticosteroids, lack of exercise, and delayed menarche all can affect the peak bone mass.⁴¹

Uveitis

According to data from population-based JIA series, uveitis occurs in 3% to 21% of patients.^{29,42,43} In the majority of cases the uveitis is “silent” and asymptomatic. Uveitis occurs more commonly in children with early-onset arthritis, and 50% to 80% test positive for ANAs by immunofluorescence. Interestingly, some geographic areas (e.g., Costa Rica, India, and South Africa) report very few or no patients with ANA-positive oligoarthritis associated with uveitis,⁴⁴ which suggests true differences in disease manifestations pertaining to immunogenetics or environmental factors, or a combination of both. Uveitis is rare among children with systemic and polyarticular RF-positive arthritis. Symptomatic uveitis occurs more often in boys and is associated with HLA-B27 and enthesitis-related arthritis.⁴³ Most cases of symptomatic uveitis are acute and episodic, but the uveitis may take a chronic course.

According to population-based data, the median age at onset of JIA associated with uveitis is 5 years (range, 1 to 16 years), that is, lower than the age at onset in the total cohort of JIA. In about 80% of patients uveitis appears within the first 4 years after arthritis onset, but late cases may occur.^{9,43,45} The uveitis is bilateral in about half of the cases.

Because the uveitis is mostly asymptomatic, a slit-lamp examination is necessary in all children with JIA for early detection of eye involvement. A cloudy light path looking like a light shaft in a smoky room is seen when the anterior chamber contains inflammatory cells and fibrin debris. The iris may demonstrate irregularities due to posterior synechiae when a bright light shines into the pupil (Fig. 101.17). The outcome is worse when uveitis occurs before or at the onset of JIA and when the uveitis is severe at onset and continually active.⁴⁶ Complications associated with ongoing active inflammation and prolonged local corticosteroid treatment are synechiae, band keratopathy, cataracts, glaucoma, and finally macular edema, phthisis, and loss of vision.⁴⁶ To avoid sight-threatening complications, the American Academy of Pediatrics Sections on Rheumatology and Ophthalmology have produced recommendations for regular eye examinations (Table 101.4) in children with JIA.⁴⁷

TABLE 101.4
American Academy of Pediatrics guidelines for screening eye examinations in juvenile rheumatoid arthritis

Type	ANA	Age at onset (years)	Disease duration (years)	Risk category	Examination frequency (months)
Oligoarthritis or polyarthritis	+	≤6	≤4	High	3
	+	≤6	>4 ≤ 7	Moderate	6
	+	≤6	>7	Low	12
	+	>6	≤4	Moderate	6
	+	>6	>4	Low	12
	–	≤6	≤4	Moderate	6
	–	≤6	>4	Low	12
Systemic disease	–	≤6	NA	Low	12
	NA	NA	NA	Low	12

Recommendations for follow-up continue through childhood and adolescence in the 2006 guidelines.⁴⁷

ANA, antinuclear antibodies; NA, not applicable.

Pain

Pain is a frequent complaint in all children, and musculoskeletal pain, headache, and abdominal pain are the most frequent types.⁴⁸ Girls and older children experience pain more often than boys and younger children, and the majority of adolescents with chronic pain report some subjective disability. Self-reported pain is influenced by previous experience, development, and beliefs as well as life-style factors, anxiety and depression, and family function.^{49,50}

Sällfors and coworkers⁵¹ found a strong influence of experienced pain in the daily life of children with juvenile arthritis. Pain created uncertainty, especially in older children, because they could never predict if it would be a “good” day with little pain or a “terrible” day with severe pain. The uncertainty came from the many social consequences, such as not being able to predict whether he or she would be able to go to school that day, whether it would be possible to take part in physical education, as well as from the increased dependence on parents at an age when increasing independence is the norm. Also, the fact that pain cannot be seen made obtaining understanding from peers difficult.

Sleep disturbance and fatigue

Sleep is of primary importance for physical and intellectual growth, and sleep disturbances that begin in childhood may persist into adulthood. Studies show that sleep disturbances are common in children with JIA and that sleep patterns in these children are different in multiple sleep domains

compared with patterns in children without disease.^{52,53} The cause is multifactorial but leads to a common endpoint of sleep fragmentation and/or deprivation. Factors that may contribute include anxiety, pain, and in rare cases breathing problems caused by micrognathia and cervical spine compromise, and autonomic nervous system imbalance. Children's self-reports reveal that sleep disturbance correlates well with pain, whereas parents' reports do not show such a correlation. This emphasizes both the importance of listening to the child's own experience and the need for good pain management programs. Sleep disturbance may lead to daytime fatigue and irritability, which in turn have effects on social life and school performance. It may also interfere with GH secretion and thus affect growth.⁵⁴

Fatigue is acknowledged as an important manifestation of rheumatic disease in adults and has also received increasing attention in children. Varni and associates⁵⁵ studied the use of the PedsQL Multidimensional Fatigue Scale in pediatric patients with rheumatic diseases and confirmed that the instrument has good validity and reliability. Clinical follow-up studies using this instrument show that fatigue is prevalent among children with JIA.⁵³ However, the findings of the instrument should be interpreted with care if the child reports pain because this may act as an important confounder and pain is shown to interfere significantly with the perception of fatigue.⁵⁶

OUTCOME

JIA may have considerable impact on physical function and psychosocial well-being throughout childhood and into adult life. To what degree the early, more aggressive, and tailored treatment of today improves outcome for the child with JIA compared with that noted in previous reports remains to be seen. Outcome is a complex phenomenon that needs to be viewed from many perspectives. Most studies have focused on traditional disease-centered outcomes, including clinical remission, physical disability, and structural damage. To get a true picture of the impact of JIA, a broader perspective that includes psychosocial well-being and quality of life as well as socioeconomic attainments must be adopted.⁵⁷ To better categorize outcome, the pediatric medical community has developed standardized outcome measures to objectively define and monitor disease activity, disease improvement, flare, and damage.⁵⁸ The Juvenile Arthritis Disease Activity Score (JADAS) is a validated measure of disease activity.⁵⁹⁻⁶¹ It is a simple composite score consisting of the patient/parent and physician global assessment, the number of active joints, and the ESR or CRP level. These same variables, together with results on the Child Health Assessment Questionnaire (CHAQ),⁶² make up the core set of outcome variables.⁵⁸ The Juvenile Arthritis Damage Index (JADI) is another validated tool aiming to score all forms of long-term articular and extraarticular morbidity in patients with JIA.^{63,64} New tools to monitor disease activity and improvement are likely to allow individually tailored early treatment with drugs demonstrated to decrease joint destruction and thereby improve the long-term outcome of JIA.

Remission

A common misconception has been that most childhood arthritis disappears in adulthood. However, ongoing or intermittent disease activity into adulthood has been found in more than half of the children in several long-term follow-up studies.^{29,37,65} The outcome of JIA is variable depending on the category and course of disease. The remission rate is highest in persistent oligoarticular arthritis (50% to 80%), whereas it is lower in extended oligoarticular arthritis and polyarticular disease (20% to 30%) and is especially low among RF-positive patients.^{7,29,35,37,66} Remission rates in studies of systemic disease are more variable (0% to 80%), probably owing to the heterogeneity of this category.^{29,35,37} The long-term remission rates in enthesitis-related arthritis as well as in juvenile psoriatic arthritis seem to be low (0% to 30% and 30% to 40%, respectively).^{7,35,37,66-68}

Continuous activity and damage

The most consistent risk factors for continued disease activity in JIA are polyarticular and extended oligoarticular disease, especially in females; elevated inflammatory markers at onset; and RF positivity. Predictors for disability and joint damage are mostly the same factors (i.e., continuous disease activity, polyarticular course, female sex, and RF positivity).⁶⁸⁻⁷⁰ Attainment of disease inactivity at least once in the first 5 years is found to be associated with less long-term joint damage and a trend toward less functional impairment.⁶⁹ In systemic JIA, children with disease onset before age 5 years, accelerated radiologic changes, pericarditis, and thrombocytosis are at higher risk for having a poor functional outcome.⁷¹

Vision

A major cause of morbidity in JIA is uveitis. Early detection and intensive treatment seem to have improved the prognosis for vision considerably. In population-based studies in Finland and the United States (Minnesota), the prognosis regarding blindness and severe vision loss is good. In the Finnish study, at a median follow-up of 7 years, one third of patients still had active uveitis, but only 3% had severe visual loss. In the study in Olmsted County, Minnesota, only 3% developed uveitis, and none had visual impairment after 8 to 24 years.^{42,72} The course of uveitis is unrelated to the course of the arthritis and may persist after arthritis has remitted. The importance of screening for uveitis (see Table 101.4) and early and intensive treatment of inflammation and its complications must be stressed. However, a few patients who do not respond even to the most intensive treatments available today still develop severely impaired vision.

Mortality

The most recent studies show no increased mortality rate in JIA, whereas in early reports mortality ranged from 2% to 7%.^{7,73,74} A small but significant increased risk of cancer is found in large epidemiologic studies of JIA. The increased risk of cardiovascular disease seen in adult rheumatic arthritis has so far not been verified in children, but there are indications of blood vessel endothelial dysfunction that may be attributed to inflammation or medications.⁷⁵ Today amyloidosis is a very rare complication of JIA in the systemic category, probably owing to the more aggressive antiinflammatory therapy given. Amyloidosis should be suspected in patients with persistent disease activity who develop proteinuria and a rising ESR with falling hemoglobin and serum albumin levels.

Functional outcome and disability

The functional outcome of JIA seems to have improved considerably over the past decades. The proportion of patients classified in Steinbrocker class III or IV in studies published after 1990 is 3% to 15%.⁷⁶ The decline in the number of patients with severe functional disability is likely due to early and more active treatment with disease-modifying antirheumatic drugs such

as methotrexate and biologic agents, treatment with intraarticular corticosteroids, and implementation of team-based comprehensive care. However, changes in the natural history of the disease and better general health status in children are possible contributing factors.⁶⁵

Functional outcomes in individual disease categories are fairly distinct when evaluated by the CHAQ.⁵⁸ Overall, 80% of patients with persistent oligoarticular JIA report no difficulties at 15-year follow-up.³⁷ However, of those with an oligoarticular extended or polyarticular arthritis, more than half develop some functional disability, and it is mainly in these categories that those with the most severe functional limitations are found, with highest rates among RF-positive patients.⁶⁶ Poor functional outcome can also be seen in patients with systemic JIA who develop polyarticular disease.

Even with aggressive treatment, a small proportion of children with JIA continue to experience poor health and psychosocial and educational limitations. A 25-year population-based follow-up study comparing juvenile rheumatoid arthritis patients with sex- and age-matched peers with no history of the disease showed that those with juvenile rheumatoid arthritis had greater disability, more pain, increased fatigue, poorer health perception, decreased physical functioning, and less involvement in exercise.⁷⁷ School attendance and participation in social activities are often influenced by the disease, but the majority of long-term follow-up studies show that educational levels and spousal relationships are similar to those of healthy control subjects.^{35,78-80} Some studies have found a lower employment rate among adults with juvenile-onset arthritis than in the background population.^{80,81}

Transition of care

Many young people have continued active disease into adulthood, and this group needs continuity of care in the transition from child-centered to adult-oriented systems. Young people should be given the chance to express their views and should be seen without their parents at visits.⁸² Continuity in health personnel, individualized timing of information provision and transition, and increasing self-advocacy over several years are important elements of a successful transition process, and this process needs time.^{83,84} Implementation of a structured and evidence-based transitional care program is recommended because it has been shown to increase health-related quality of life in adolescents moving from pediatric to adult care.⁸⁵

102

Etiology and pathogenesis of juvenile idiopathic arthritis

■ RACHELLE DONN

- Juvenile idiopathic arthritis (JIA) encompasses several subgroups that have distinct clinical, immunologic, and genetic differences.
- JIA subgroups are each complex traits with contributions from both genetic and environmental parameters.
- Synovium and cartilage are both affected. Triggers for initiation and progression of the pathology that is manifested as JIA have not been identified.
- Association and linkage to HLA loci have been confirmed for certain JIA subgroups.
- A limited number of non-HLA loci have been shown to be significant in conferring susceptibility to JIA.

INTRODUCTION

Juvenile idiopathic arthritis (JIA)* is the most common rheumatic disease of childhood. It encompasses a heterogeneous group of chronic arthropathies, all of which share persistent idiopathic inflammation of one or more synovial joints. The subtypes of JIA differ in their clinical manifestations, prognosis, and specific autoimmune characteristics.

Classification of chronic arthritis of childhood onset remains problematic. Different classifications exist in the literature, be it International League of Associations for Rheumatology (JIA), European Leagues Against Rheumatism (juvenile chronic arthritis [JCA]), or American College of Rheumatology (juvenile rheumatoid arthritis [JRA]) naming conventions (see Chapter 100). This makes comparisons of the research literature difficult.

PATHOLOGY

JIA is an inflammatory disorder that primarily affects synovial joints.

The clinical characteristics of joint involvement vary across the different JIA subgroups but are generally manifested as swelling, stiffness, pain, or loss of function of the affected joint (or any combination). The disease process of JIA includes synovial hyperplasia causing soft tissue swelling, joint effusion, and cartilage destruction, which result in bone erosions. Lymphocytes, plasma cells, macrophages, and dendritic cells are all present in increased number within the inflamed JIA joint.² The typical manifestation of oligoarthritis is shown in Figure 102.1, together with a schematic representation of the pathology within the JIA-affected joint.

The immunopathogenic mechanisms underlying JIA have been the subject of intensive study but have not yet been elucidated. The detection of T cells and chronic synovial inflammation has indicated cellular mediation, whereas the finding of immune complexes and complement has suggested a possible B-cell-mediated response.

Synovial fluid

The volume of synovial fluid in affected joints is increased in JIA, with viscosity being decreased mainly because of reduced concentrations of hyaluronic acid. Synovial fluid contains various inflammatory cells, including

neutrophils, plasma cells, dendritic cells, and a high proportion of T cells expressing markers of activation.³ These cells are most likely to extravasate from the inflamed synovial lining. Mediators of inflammation such as cytokines and cleavage products of the complement system are also abundant.

Synovial tissue

One of the hallmarks of the pathology of JIA and, in particular, rheumatoid factor–positive (RF+) polyarticular JIA is the tumor-like expansion of inflamed synovial tissue, or pannus, which causes much of the joint damage in this disease.⁴ With progression of the disease, the pannus spreads over the synovial space and adheres to intraarticular cartilage. It is in the areas of pannus-cartilage junctions that the cartilage eventually degrades (Fig. 102.2). Such expansion results from invasion of the synovial tissue by inflammatory cells recruited from the peripheral circulation and the proliferation of synoviocytes.

Cartilage

Cartilage is a primary target organ that is affected as part of the pathogenic process of JIA.^{5–7} Superficial cartilage thinning is a feature of early and untreated JIA. Complete cartilage destruction and cartilage erosions leading to bone erosions can occur with long-standing disease.^{8,9} Magnetic resonance imaging enhanced with gadolinium tetraazacyclododecane tetraacetic acid increases sensitivity for detection of the inflammatory changes in JIA¹⁰ (Fig. 102.3).

T cells and juvenile idiopathic arthritis

CD4+ T lymphocytes are the predominant cell population in JRA synovium and exhibit the phenotypic and functional characteristic of cells that have previously undergone activation *in vivo*.⁴ These characteristics include expression of interleukin-2 (IL-2) receptors (CD25), early activation antigen CD69, CD45RO (memory phenotype), very late activation antigen type 1 (VLA-1), and HLA class II antigens.³ It has been suggested that such activation might be induced by an autoantigen located in the inflamed joints.

Analysis of several experimental antigen-driven models has shown that antigen-specific T cells often make up only a very small proportion of all T cells present at the site of the immune response, thus suggesting that most of the other cells are recruited in a nonspecific manner. Extrapolation of these data to the pathogenesis of JRA suggests that the numbers of T cells critical for an autoimmune response in inflamed joints may be very small.

Regulatory T cells, type 17 helper T cells, and juvenile idiopathic arthritis

CD4+ helper T (Th) cells help regulate the immune response. Characterization of effector Th cell subsets by their differential cytokine production has resulted in the Th1-Th2 paradigm. Th1 cells produce interferon- γ and regulate antigen presentation and immunity against intracellular pathogens. Th2 cells produce IL-4, IL-5, and IL-13 and mediate some humoral responses and immunity against parasites. However, observations by several different groups have described the proinflammatory cytokines IL-17 and IL-17F to be expressed by distinct Th cells that did not express either interferon- γ or IL-4. This has resulted in the discovery of Th17 cells as a Th lineage independent of Th1 or Th2 cells.

Regulatory T (Treg) cells have the phenotype CD4+CD25+. These spontaneously occurring T cells can actively and dominantly prevent the activation and effector function of autoreactive T cells that escape other mechanisms of tolerance. A role for CD4+CD25+ Treg cells in the

*This chapter essentially focuses on JIA (as defined by the International League of Associations for Rheumatology¹) but refers to the terms cited in the original papers throughout.

Fig. 102.1 (a) Typical manifestation of oligoarthritis. (b) Joint in which one side is normal and the other shows the characteristic pathology of juvenile idiopathic arthritis (JIA). (a, Original from <http://pediatric-orthopedics.org/from-toddler-to-adolescence/41-juvenile-rheumatoid-arthritis.html>; b, modified from Chapel H, Haeney M, Misbah S, et al. *Essentials of clinical immunology*. (b) Photomicrograph of a section taken at the articular margin of the specimen demonstrated in (a) showing a destructive inflammatory pannus extending onto the articular surface. (With permission from Bullough PG. *Orthopaedic pathology*. 3rd ed. London: Mosby-Wolfe; 1997.)

pathogenesis of JIA has been considered by a number of groups.¹¹⁻¹⁴ More recently, a role of IL-17-producing T cells has been shown. IL-17+ T cells are enriched within the joints of children with JIA, and the number of such cells was found to be higher in patients with extended oligoarthritis than in those with the milder persistent oligoarthritis. An inverse relationship between IL-17+ T cells and Fox3P+ Treg cells was found.¹⁵ This suggests that Th17 cells are contributing to the joint pathology of JIA and that the balance between IL-17+ T cells and Treg cells may influence disease outcome.

Macrophage and fibroblast contribution to the pathogenesis of juvenile idiopathic arthritis

Increased numbers of macrophages and dendritic cells and proliferation of fibroblast-like and macrophage-like synoviocytes are typical features of JRA

synovium.⁴ The abundance of cytokines secreted by these cells provides further evidence for a major role of these cells in perpetuation of the synovial inflammation. Martini and colleagues¹⁶ in 1986 noted high spontaneous production of IL-1 by mononuclear cells derived from the peripheral blood of patients with juvenile arthritis. More recently, an abundance of IL-1-producing macrophages has also been demonstrated in inflamed JRA synovial tissue.¹⁷

Analysis of tumor necrosis factor (TNF) expression and the distribution of TNF receptors in JRA synovial tissues provided strong evidence for the role of both TNF- α and TNF- β in amplification of the synovial inflammation in JRA.¹⁸ Numerous cells staining for TNF- α were found in the majority of synovial tissue samples, and the pattern of distribution of TNF- α cells was similar to the distribution of macrophages. The level of expression of TNF- α correlated closely with the degree of inflammatory infiltration of the synovial membrane.

Fig. 102.3 A T2-weighted fat-suppressed image in a 10-year-old child shows high signal from both the synovium and synovial fluid, which are difficult to distinguish. Numerous erosions, cartilage loss, and fat pad irregularity are seen on this image. (Image reproduced, with permission, from Gardner-Medwin J, Southwood T. *Current developments in juvenile arthritis. Topical Reviews No. 5, Reports on Rheumatic Diseases, Series 4, 2001. Published by the Arthritis Research Campaign. Available at www.arc.org.uk*.)

IL-6, another macrophage-derived product, has been consistently found in the synovial fluid of patients with JIA. More importantly, in systemic-onset JIA, IL-6 concentrations are increased not only in the synovial compartment but also in serum, and serum concentrations of IL-6 protein correlate with the extent of joint involvement and peripheral thrombocytosis. High levels of expression of IL-6 in synovial tissue samples have been shown to distinguish patients with systemic JRA, even at later stages of the disease.^{19,20}

B-cell contribution to the pathogenesis of juvenile idiopathic arthritis

B-cell activity

Although macrophages and T cells are usually more numerous in inflamed synovial tissue, B-cell activity also appears to be enhanced in both peripheral blood and the synovial compartment. Lindblad and associates²¹ described synovial tissue specimens from patients with juvenile arthritis that contained significantly increased numbers of focally aggregated immunoglobulin-synthesizing cells. As a consequence of increased B-cell activity, hyperglobulinemia and circulating immune complexes, antinuclear antibodies (ANAs), and RFs are common findings in many patients with JIA.

Rheumatoid factor (RF)

RFs, or autoantibodies directed against the Fc region of human IgG, are found in the serum and synovial fluid of the majority of patients with rheumatoid arthritis (RA). RF can be detected only rarely in patients with JIA by the classic Rose-Waaler reaction or latex fixation method, although the probability of finding RF increases with the age and duration of the disease. Allen and Kunkel²² demonstrated a so-called hidden RF defined as IgM 19S antiglobulin. This antiglobulin is “hidden” because of its occupied binding sites. Gel filtration at acid pH dissociates IgM from IgG and allows IgM RF to fix complement in hemolytic assays. This technique makes it possible to detect the presence of RF in a much larger proportion of patients with JIA, specifically the polyarticular subgroup.

Anti-cyclic citrullinated peptide antibodies

Citrulline is a translational modification of the amino acid arginine by peptidyl arginine deiminase (PAD). Citrulline becomes part of a protein following posttranslational modification by PAD enzymes. Antibodies to citrullinated proteins have been shown to aid in the determination of disease prognosis in adult patients with RA. The autoantibody system

involved includes antiperinuclear factor, antikeratin antibodies, antifilaggrin antibodies, anti-citrullinated fibrin antibodies, and anti-Sa (citrullinated vimentin) antibodies. A number of studies have now evaluated anti-cyclic citrullinated peptide (anti-CCP) antibody levels in patients with JIA. These studies show that anti-CCP positivity is significantly raised only in children with RF+ polyarticular JIA. Specifically, Ferucci and colleagues²³ found anti-CCP antibody formation in HLA-DR4+ cases, and the anti-CCP antibodies were associated with polyarticular onset and erosive disease.

Antinuclear antibodies (ANAs)

The reported incidence of ANAs in patients with juvenile arthritis varies from 4% to 88%, depending on the clinical subtype and the laboratory technique used.²⁴ ANAs are uncommon with systemic-onset disease, whereas more than 50% of children with oligoarticular JCA have ANAs in their serum. Children who are ANA+ carry an especially high risk for the development of chronic anterior uveitis.

The full specificity of these antibodies remains to be determined. Some studies have indicated that ANAs in most patients are directed to a ribonucleoprotein that requires both RNA and protein components for antigenic integrity. Szer and coworkers²⁵ concluded that ANA specificity profiles were highly individual and did not appear to correlate with disease subtype or activity. Several studies have revealed that antibodies to many antigens typical of other rheumatic diseases—for example, extractable nuclear protein, centromere proteins, scleroderma Scl-70, Ro, La, and double-stranded DNA—are generally absent in JIA. More recently, antibodies to the 45-kDa DEK nuclear antigen, a putative oncoprotein, have been associated with the oligoarticular type of JCA, particularly in patients with a history of iridocyclitis. However, the presence of these antibodies does not appear to be limited to or specific for JIA.

GENETIC FACTORS

Genetic epidemiology

Evidence for a genetic component of a disease can come from a variety of sources, such as twin, family, or case-control association studies. The degree of disease concordance in monozygotic (MZ) twins gives an indication of the level of involvement of genetic factors within a given disease. An alternative estimate of the genetic component of a disease can be obtained from family studies by using the sibling recurrence risk, or lambda *s* (λ_s), calculated as the prevalence of the disease in siblings of affected individuals divided by the prevalence of the disease in the general population.

The largest study of both affected sibling pairs (ASPs) and twins with JRA comes from the National Institute of Arthritis, Musculoskeletal and Skin Diseases (NIAMS)-sponsored Research Registry for JRA. Of 118 ASPs on the register in 2000, there were 14 pairs of twins in which both twins had arthritis.²⁶ One pair consisted of a girl with polyarticular JRA and a boy with pauciarticular JRA. The other 13 pairs (11 MZ and 2 of unknown zygosity) were concordant for gender (9 female, 4 male), disease onset (10 pauciarticular, 3 polyarticular), and disease course (8 pauciarticular, 5 polyarticular).

In a Finnish study of JIA multicase families, eight sets of twins were identified, two of which were concordant for arthritis. A concordance rate of 25% for a disease with a population prevalence of 1 per 1000 implies a staggering relative risk of 250 for JIA in an MZ twin.²⁷ By comparison, for adult RA the risk to an MZ twin has been reported to be 12 to 62 (reviewed in reference 28).

As noted, the largest series of ASPs has been collected as part of NIAMS' JRA registry. In 1997 the registry contained a series of 71 ASPs; 63% were concordant for gender and 76% for onset type, higher than expected based on comparisons with non-ASP populations. This study gave an estimate of the λ_s for JRA of approximately 15, a value similar to that seen with insulin-dependent diabetes mellitus and multiple sclerosis. It also provided evidence that this value is likely to differ between subtypes, with the strongest genetic component being attributable to the pauciarticular JRA subtype.^{29,30} The most recent report from the registry includes 183 ASPs from 164 families, 19 of which are twin pairs.³¹ The degree of disease-onset-type concordance between the ASPs is relatively high, 53% concordant for pauciarticular onset and 19% for polyarticular onset. The concordance is, however, markedly less for systemic-onset disease. The clinical manifestations seen in the ASPs are very similar to those of a comparative simplex JRA study population, with the exception of the number of affected joints at the onset of JRA in the polyarticular-onset disease group.³¹ Among the ASPs, age at the onset of JRA (sibling 1 versus sibling 2) was not significantly different. However, the disease does not develop in ASPs at the same point in real time (mean

real-time difference of 5.1 years). Familial aggregation was marked for tenosynovitis (λ s of 29.5), leukocytosis (λ s of 25), and RF (λ s of 11). Such familial aggregation of clinical features in ASPs adds strongly to the evidence of a genetic background for the disease.

Similarly, from Finland, 49 ASPs from 37 families were identified in a population of approximately 2000 with JIA. Within the ASPs, little difference was found in either onset type (57% concordance in ASPs) or disease course (61% concordance in ASPs) when compared with a population-based JIA series. Given a population prevalence of JIA in Finland of approximately 1 per 1000, this study suggests that the λ s for JIA is around 25, again supporting the idea of a substantial genetic component in the etiology of JIA.³²

HLA associations

Much of the genetic work in the past 3 decades has centered around HLA genes. A complete description of the HLA system can be found in Chapter 11. The fact that HLA molecules play a central role in the immune system has led to HLA genes being considered as candidates in association studies in many diseases, particularly those thought to have an immune basis such as JIA. A summary of HLA class I and class II associations with different subgroups of juvenile arthritis is presented in Table 102.1.

HLA linkage and juvenile idiopathic arthritis

A number of studies have confirmed the HLA associations by establishing linkage. Moroldo and colleagues³³ showed linkage to both HLA class I and class II with the transmission disequilibrium test (TDT) in patients with pauciarticular-onset JRA. HLA-A2, HLA-B27, HLA-B35, HLA-DR5, and HLA-DR8 all showed excess transmission, whereas HLA-DR4 was under-transmitted. A second study using the TDT in a U.K. cohort of patients with oligoarticular JIA confirmed the linkage.³⁴ Here, HLA-A2, HLA-DRB1*08, and HLA-DRB1*11 were overtransmitted and HLA-A3, HLA-DRB1*04, and HLA-DRB1*07 under transmitted. This study demonstrated that the effects at these two loci were independent. Finally, linkage analysis using the ASPs within the NIAMS-sponsored registry for JRA has confirmed linkage of pauciarticular JRA and HLA-DR and also established linkage for polyarticular JRA and HLA-DR.³⁵ Prahalad and associates³⁵ estimated that the proportion of the sibling recurrence risk attributable to HLA (λ_{HLA}) is 2.5, thus indicating that HLA accounts for 17% of the total genetic component of pauciarticular JIA. Hence, other non-HLA genes must play a role in susceptibility.

TABLE 102.1
HLA class I and class II associations and juvenile arthritis

HLA association	Patient subgroup
Class I	
HLA B27	Male late-onset pauciarticular Enthesitis-related arthritis
A2	Pauciarticular and young age at disease onset
Class II	
HLA-DRB1*11 (a subtype of HLA-DR5) and HLA-DRB1*08	Early-onset pauciarticular/oligoarthritis
HLA-DRB1*04 and HLA-DRB1*07 [†]	Early-onset pauciarticular/oligoarthritis
HLA-DPB1*0201	Early-onset pauciarticular Persistent and extended oligoarthritis
HLA-DR8/HLA-DRB1*08	RF-negative polyarthritis
HLA-DQ4 (DQA1*0401/DQB1*0402)	RF-negative polyarthritis
HLA-DP3/DPB1*0301	RF-negative polyarthritis
HLA-DR4	RF-positive polyarthritis
HLA-DR5 and HLA-DR8	Systemic onset
HLA-DRB1*11	Systemic onset
HLA-DR4	Systemic onset

[†]Decreased risk for susceptibility. All the other HLA associations listed in the table confer an increased risk for susceptibility.

Non-HLA candidate genes and juvenile idiopathic arthritis

Multiple different non-HLA genetic loci have been investigated in children with arthritis (reviewed in reference 36). Arguably, any association reported is only of value in helping decipher the etiopathogenesis of JIA if the genetic findings are replicated and provide robust evidence of a true effect. To date, for only a handful of these candidate genes has replication been achieved (Table 102.2).³⁷⁻⁴³

Genome-wide association studies and juvenile idiopathic arthritis

Genome-wide association studies (GWASs) examine, in an unbiased analysis, hundreds of thousands of single nucleotide polymorphism (SNP) variants in a large number of unrelated cases and controls. In 2007 the U.K. Wellcome Trust Case Control Consortium published its seminal manuscript detailing a GWAS of 14,000 cases of seven common diseases and 3000 shared controls.⁴⁴ This represented a turning point in the approach to studying complex genetic diseases.

A rich seam of positive associations for JIA has been garnered by studying GWAS loci associated with other clinical conditions that may have some degree of disease overlap with JIA. In particular, multiple SNP associations found to be positive from RA GWASs are also positive for JIA⁴⁵⁻⁴⁷ (Table 102.3). The overlap extends, however, to other autoimmune and inflammatory diseases, as summarized in Table 102.3.

To date, only two JIA GWASs have been performed. The first, by Hinks and coworkers,⁴⁸ was of modest size and used the Affymetrix GeneChip 100K arrays in only 279 cases and 184 controls. This identified a replicated association with SNPs in the *VTCN1* gene.

More recently, Thompson and colleagues⁴⁹ used the high-density Affymetrix Genome-Wide SNP 6.0 Array (Million SNP array) in a well-powered study and found replicated evidence of association for SNPs at 3q13, within *C3orf1* and near *CD80*, and at 10q21, near *JMJD1C* with JIA. These findings were supported by gene expression analysis.

TABLE 102.2
Non-HLA genetic loci associated with juvenile idiopathic arthritis that have been independently confirmed

Gene	References
<i>PTPN22</i>	Hinks, ³⁷ Viken ³⁸

TABLE 102.3
GWAS-identified loci associated with juvenile idiopathic arthritis and multiple other autoimmune diseases

Gene	Autoimmune diseases
<i>PTPN22</i>	RA, SLE, AITD, T1DM, MS, celiac disease, autoimmune hepatitis
<i>PTPN2</i>	
<i>CCR5</i>	RA, MS, T1DM
<i>COG6</i>	RA, T1DM, psoriasis
<i>ANGPT1</i>	RA
<i>IL2RA</i>	RA, T1DM
<i>STAT4</i>	RA, SLE
<i>TNFAIP3</i>	RA, SLE, celiac disease
<i>C12orf30</i>	T1DM
<i>TRAF1/C5</i>	RA, SLE
<i>PRKCQ</i>	RA, celiac disease

AITD, autoimmune thyroid disease; GWAS, genome-wide association study; MS, multiple sclerosis; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus; T1DM, type 1 diabetes mellitus.

ENVIRONMENTAL FACTORS

In an attempt to identify the causative agent or agents implicated in the etiopathogenesis of juvenile arthritis, associations with a number of potential viral and bacterial pathogens have been sought. A self-limited polyarthritis can follow a wide variety of viral infections, including Coxsackie B virus, Epstein-Barr virus, parvovirus, and rubella.^{50,51} Studies reporting positive findings of viral antigens in JCA patients, however, are limited. Rubella virus has been implicated for some time,⁵² and an arthritis very similar to pauciarticular JCA develops in a small proportion of individuals who received rubella immunizations.⁵³

Pritchard and coworkers⁵⁴ noted birth date clustering among polyarticular JCA patients in whom progressive disease developed after the appearance of influenza A H₃N₂ in 1977. These patients had all been born in 1963, a year in which an epidemic of influenza A H₂N₂ had occurred. Raised levels of antibody to H₂N₂, the strain of influenza A prevalent at the time at which they were born, was recorded in this cohort. This led to the suggestion that arthritis developed in these individuals in 1977 because they had been pre-sensitized to influenza A by contact with the earlier strain when *in utero*. In a follow-up study on a similar cohort, influenza-specific cytotoxic T-cell clones were identified in blood and synovial fluid, but no evidence of sequestration to the joints of such clones was found.⁵⁵

The clinical features of systemic-onset JIA are particularly suggestive of a viral origin, and rising antibody titers to Coxsackie B4 were found during the acute stages in such patients.⁵⁶ Feldman and coauthors addressed seasonal differences in the onset of systemic-onset JRA by examining data collected from all patients with systemic-onset disease from 1980 to 1992 seen at pediatric rheumatology clinics across Canada. The onset pattern of systemic-onset JRA was then compared with the incidence data on viral infection.⁵⁷ Across Canada the onset of systemic-onset JRA was found to be constant across the seasons. However, in the prairie region a significant

seasonal pattern was detected, with peaks occurring in the autumn and early spring, but there was no evidence that viral infection correlated with disease incidence. Furthermore, a large multicenter European study failed to show a seasonal pattern in the onset of systemic or any other form of JCA.⁵⁸

HLA-B27-associated forms of JCA may be triggered by bacterial infections. A bacterium-specific synovial cellular immune response was found in spondyloarthritis patients to *Chlamydia trachomatis* and *Yersinia enterocolitica*, organisms known to be important in reactive arthritis.⁵⁹ In addition, an immunodominant epitope, Gro EL of *Escherichia coli* heat shock proteins, is one target of immune responsiveness in HLA-B27+ JCA.⁶⁰

Cellular immune responses to dnaJ, an *E. coli* heat shock protein, were found to be related to disease activity in a study of 25 JRA patients.⁶¹ No immunologically cross-reactive human homologue to this bacterial dnaJ has yet been identified.

Specific humoral reactivity against two proteins from Epstein-Barr virus, Bolf1 and Balf2, has been described in oligoarticular JIA cases. These viral proteins share sequence homologies with HLA antigens known to be associated with this patient subgroup.⁶²

CONCLUSION

JIA is an intriguing collection of phenotypes. Many diverse features occur and a limited number of unifying ones (onset before 16 years of age, chronic synovitis of joints). Much research still needs to be done to elucidate the etiopathogenesis of JIA. Despite some advances in SNP association studies, multiple other facets need to be considered to understand a complex genetic condition such as JIA. Analysis of gene-gene as well as potential gene-environment interactions needs to be done, but the numbers involved to make such studies feasible is large and will be achieved only via international consortia.

Management of juvenile idiopathic arthritis

■ PHILIP J. HASHKES ■ RONALD M. LAXER

MEDICAL MANAGEMENT

- Early “aggressive” therapy has resulted in improved outcomes for patients with juvenile idiopathic arthritis (JIA).
- Treatment is individualized according to the clinical manifestations of JIA and the presence of uveitis.
- Many new medications with effects on various immunologic pathways, especially biologic modifiers, are available for children.
- The American College of Rheumatology has developed recommendations for the treatment of JIA based on various clinical findings, prognostic signs, and clinical severity.

SURGICAL MANAGEMENT

- The need for surgical therapy may be decreasing as a result of improved medical management.
- Children have several specific issues with regard to arthroplasty.

OTHER ISSUES OF MANAGEMENT

- Greater attention needs to be directed to the treatment of pain.
- Issues of growth need to be addressed.
- Physical and occupational therapy, as well as assistive devices, splints, and orthotics, is an important part of therapy (addressed in detail in Chapter 106).

INTRODUCTION

Treatment of juvenile idiopathic arthritis (JIA) has changed dramatically in the past 25 years. The first change occurred in the late 1980s with the increasing use of intraarticular corticosteroid injections in children with oligoarthritis and the use of methotrexate (MTX) in those with polyarthritis. The second major change occurred in the late 1990s with the development of biologic modifiers, first anti-tumor necrosis factor (TNF) medications and later biologic modifiers targeting other cytokines involved in the inflammatory process or lymphocyte receptors.

The discovery of new effective medications was facilitated by the development of research networks. The Pediatric Rheumatology Collaborative Study Group in North America and the Pediatric Rheumatology International Trials Organization in Europe and elsewhere have conducted high-quality, multicenter, multinational controlled trials. Another important development was the validation of efficacy outcome measures (Table 103.1). The American College of Rheumatology (ACR) Pediatric 30 (Pediatric ACR30) defines patients as responders or nonresponders (Box 103.1).¹ This outcome measure has been modified for systemic arthritis studies (includes the absence of fever and characteristic rash) and to define a flare outcome in drug withdrawal studies, used mainly for studies of rapidly acting biologic modifiers. However, patients and physicians expect to achieve much better than a Pediatric ACR30 response. Thus, most new studies also report the Pediatric ACR50/70/90 and even ACR100 response criteria. Preliminary definitions of three levels of remission have been reported: inactive disease, clinical remission on medication, and clinical remission off medication (Box 103.2).² Several functional tools and quality-of-life tools have been validated and adapted for JIA. Other composite/multidimensional and long-term outcome tools are being developed or are in the process of validation (see Table 103.1).

The treatment philosophy for JIA has also undergone transformation. In the past, treatment was based on the “pyramid” approach, which initially used various types of nonsteroidal antiinflammatory drugs (NSAIDs) and corticosteroids and gradually advanced to other medications. Studies in the late 1980s indicated that earlier assumptions on the course and outcome of JIA were incorrect. Radiologic joint damage, previously thought to take place late in the course of the disease, occurs in most patients with systemic arthritis and polyarthritis within 2 years and in those with oligoarthritis within 5 years of disease onset and perhaps earlier as shown by magnetic resonance imaging (MRI).

The assumption that JIA will usually resolve by adulthood is also incorrect. Studies in the “pre-MTX era” have shown that between 50% and 70% of patients with polyarthritis or systemic arthritis and 40% to 50% of those with oligoarthritis continue to have active disease in adulthood.³ Only a minority of patients attained clinical remission off medications for at least 2 years, and only 4% attained a remission for at least 5 years.⁴ Between 30% and 40% of patients had significant long-term disabilities, including unemployment, and between 25% and 50% required major surgery, including joint replacement.³ Leg-length inequality and muscle atrophy near affected joints developed frequently in patients with oligoarthritis. Patients with systemic arthritis have an increased mortality rate. Thus, the burden of disease on the patient, family, and ultimately society is large, and it is crucial that the disease be recognized and treated early and aggressively before the soft tissue deformities and joint damage become irreversible.

Several predictors of a poor outcome can help determine which patients require early aggressive therapy. Patients with polyarthritis (especially when involving the hip and cervical spine) and positive rheumatoid factor (RF), anti-citrullinated peptide antibodies (ACPAs), the presence of HLA-DR4, nodules, early-onset symmetric small-joint involvement, and existing radiologic damage have a worse prognosis.³ Patients with systemic arthritis who are dependent on corticosteroids for control of systemic symptoms and have a platelet count greater than 600,000/mm³ after 6 months of disease have a worse outcome.³

Treatment of JIA depends to a large extent on the disease subtype (Table 103.2) and clinical findings and combines antiinflammatory and immunomodulatory medications with physical and occupational therapy, an occasional need for surgery, nutritional support, and psychosocial and educational partnership with patients and parents. The treatment plan should be as simple as possible based on studies showing relatively low adherence to recommendations, both to medications and, to a larger extent, to physical therapy and exercise. Fortunately, many of the current JIA medications are given once weekly or less often (many by injection or infusion), which makes it easier to adhere to the treatment plan.⁵ The increased efficacy has decreased the rate of many complications and deformities, thus somewhat diminishing the roles of rehabilitation therapy and surgery as compared with the past. This chapter presents the new ACR recommendations for medical treatment of the arthritis of JIA⁶ based on the subtypes of JIA (including uveitis) and offers a rational approach to treatment of the various clinical manifestations of the disease. This is followed by a detailed discussion of the individual medications (including new biologic-modifying drugs) used to treat JIA and other components of treating JIA, such as managing pain and surgical interventions.

TREATMENT RECOMMENDATIONS FOR THE SUBTYPES OF JUVENILE IDIOPATHIC ARTHRITIS (Table 103.3)

The current aim of treatment is to achieve a state of disease inactivity. Treatment recommendations published by the ACR in 2011 used the best avail-

TABLE 103.1
Assessment and outcome measure tools for juvenile idiopathic arthritis

Domain	Assessment tools
Disease activity	Active joint count, acute-phase reactants, Juvenile Arthritis Disease Activity Score (JADAS)
Global assessment	Physician, patient visual analog scale
Multidimensional assessment	Juvenile Arthritis Multidimensional Assessment Report (JAMAR)
Functional assessment	Childhood Health Assessment Questionnaire (CHAQ), Juvenile Arthritis Functional Assessment Report (JAFAR), Juvenile Arthritis Functional Status Index (JASI)
Quality-of-life assessment	Childhood Health Questionnaire (CHQ), Peds-Quality of Life (QOL)—Rheumatology subset, pain visual analog scale
Radiologic damage	Poznanski, Dijkstra scores
Disease-related irreversible damage	Juvenile Arthritis Damage Index (JADI)
Clinical trial outcome measures	American College of Rheumatology Pediatric 30 (Pediatric ACR30) (modified for systemic arthritis and flare) criteria for inactive disease or clinical remission

TABLE 103.2
Subtypes of juvenile idiopathic arthritis

Subtype	Proportion of patients (%)
Systemic arthritis (starts with a spiking fever, rash)	5-10
Oligoarthritis (≤ 4 joints in the first 6 mo)	40-50
Persistent oligoarthritis course	25-35
Extended polyarticular course	15-20
Polyarthritis rheumatoid factor negative (≥ 4 joints in the first 6 mo)	25-30
Polyarthritis rheumatoid factor positive	5-10
Enthesitis-related arthritis (formerly called spondyloarthritis)	Undetermined
Psoriatic arthritis	5
Other (fits none or >1 category)	Undetermined

Adapted from Petty RE, Cassidy JT. Chronic arthritis in childhood. In: Cassidy JT, Petty RE, Laxer RM, Lindsley CB, editors. *Textbook of pediatric rheumatology*. 6th ed. Philadelphia: Saunders; 2011, p. 212.

TABLE 103.3
Major medications and indications for treatment of juvenile idiopathic arthritis

Medication	Arthritis subtype	Indication
NSAIDs	All types	Symptomatic: pain, stiffness, fever, antiinflammatory in mild cases
Intraarticular corticosteroids	All types, mainly oligoarthritis	Injection of few active joints
Systemic corticosteroids	Systemic, polyarthritis	Fever, serositis, bridging medication, macrophage activation syndrome
Methotrexate	All types, less effective for systemic and enthesitis-related axial disease	Disease modifying
Leflunomide	Polyarthritis	Disease modifying
Sulfasalazine	Oligoarthritis, polyarthritis, enthesitis-related peripheral disease	Disease modifying
Cyclosporine	Systemic	Macrophage activation syndrome
Thalidomide	Systemic	Biologic modifier
Anti-TNF (etanercept, infliximab, adalimumab)	Polyarthritis, enthesitis-related, uveitis (infliximab, adalimumab), less effective for systemic disease	Biologic modifier
Abatacept	Polyarthritis, including anti-TNF failure, uveitis	Biologic modifier
Anti-IL-1 (anakinra, rilonacept, canakinumab)	Systemic	Biologic modifier
Anti-IL-6 (tocilizumab)	Systemic, polyarthritis	Biologic modifier
IVIg	Systemic	Steroid sparing

IL-1, interleukin-1; IVIg, intravenous immune globulin; NSAIDs, nonsteroidal antiinflammatory drugs; TNF, tumor necrosis factor.

BOX 103.1 PEDIATRIC ACR30 FOR JUVENILE IDIOPATHIC ARTHRITIS TRIALS

1. Active joint count (joints with swelling or tenderness/pain on motion with limitation of motion)
2. Joints with limited range of motion
3. Parent/patient global assessment (measured on a 0 to 10 visual analog scale)
4. Physician global assessment (measured on a 0 to 10 visual analog scale)
5. Laboratory measure of inflammation (erythrocyte sedimentation rate, C-reactive protein)
6. Functional assessment (Childhood Health Assessment Questionnaire)

Note: A patient's disease is considered to have responded if at least three variables have improved by at least 30% and not more than one variable has worsened by more than 30%. From Giannini EH, Ruperto N, Ravelli A, et al. Preliminary definition of improvement in juvenile arthritis. *Arthritis Rheum* 1997;40:1202-9.

BOX 103.2 CRITERIA AND TYPES OF REMISSION* IN JUVENILE IDIOPATHIC ARTHRITIS

1. No active arthritis
2. No fever, rash, serositis, splenomegaly, or generalized lymphadenopathy attributable to juvenile idiopathic arthritis
3. No active uveitis
4. Normal erythrocyte sedimentation rate or C-reactive protein
5. Physician's global assessment of disease activity at the best score possible for the instrument used

*Clinical remission on medication: 6 continuous months of inactive disease during medication; clinical remission off medication: 12 months of inactive disease without any antiarthritis (and antiuveitis) medication.

From Wallace CA, Ruperto N, Giannini E, et al. Preliminary criteria for clinical remission for select categories of juvenile idiopathic arthritis. *J Rheumatol* 2004;31:2290-4.

able evidence to propose treatment based on the disease course of the individual patient (see Table e103.1).⁶ Clinical scenarios that included features of a poor prognosis and disease activity levels (low, moderate, and high) were developed for each JIA subtype, and treatment recommendations were developed accordingly.⁶ A summary of these recommendations follows.

Oligoarthritis

Patients with low disease activity (based on the number of active joints, erythrocyte sedimentation rate [ESR], C-reactive protein [CRP], physician and patient or parent global assessments) and no features of a poor prognosis (arthritis of the hip, cervical spine, wrist, or ankle with prolonged marked elevation of ESR/CRP or radiographic damage) may respond to NSAIDs. In patients not responsive to NSAIDs after 2 months or in patients with local complications, including flexion contractures and leg-length discrepancies, intraarticular corticosteroid injections with triamcinolone hexacetonide are effective in many patients (Fig. 103.1). If the response lasts less than 4 months or extended oligoarthritis develops, treatment should proceed as for patients with polyarthritis. For patients with high disease activity and features of a poor prognosis, MTX should be initiated (or leflunomide if MTX is not tolerated). Patients who fail to respond to MTX should start an anti-TNF medication. Sulfasalazine should be initiated in patients with enthesitis-related arthritis who have peripheral oligoarthritis with at least moderate disease activity.

Polyarthritis course (regardless of onset)

NSAID monotherapy for longer than 2 months is inadequate to treat polyarthritis, even in patients with low disease activity (same parameters as for oligoarthritis) and no poor prognostic features (arthritis of the hip or cervical spine, positive RF or APCAs, or radiographic damage) (Fig. 103.2). MTX with adjunctive NSAIDs or intraarticular corticosteroid injections should be prescribed for NSAID failure or patients with high disease activity or moderate disease activity and poor prognostic features. Leflunomide may be considered as well (mainly in patients intolerant of MTX). Failure to respond to 3 to 6 months of MTX or leflunomide treatment (with moderate to high disease activity or with low disease activity, respectively) is an indication for initiation of an anti-TNF medication, again with adjunctive NSAIDs or intraarticular corticosteroid injections. Patients who fail 4 months of this treatment with at least moderate disease activity should be switched to a second anti-TNF medication, abatacept or tocilizumab. Occasionally,

systemic corticosteroids may be necessary as a bridging medication or during flares, but there is no evidence that systemic corticosteroids are disease modifying. Though not yet studied in controlled studies involving children, other medications (e.g., rituximab) and combination therapy effective for rheumatoid arthritis may be beneficial, especially in patients with positive RF or APCAs.

Systemic arthritis

Many advances in the treatment of systemic arthritis have recently been made (Fig. 103.3). For patients with active systemic features (with or without arthritis), a short course of NSAID monotherapy may be indicated in the initial workup of these patients but is not considered appropriate in those with high fever and a physician global assessment score of greater than 7 of 10. For such patients, systemic corticosteroids are often needed for symptomatic relief. No evidence has shown a preferred method of corticosteroid administration, although one controlled study found that patients administered intravenous methylprednisolone early needed fewer total systemic corticosteroids than did patients starting corticosteroids orally. Initiation of anakinra was recommended for all patients with active fever and features of a poor prognosis, as well as for patients who sustain or develop fever while taking corticosteroids. Canakinumab, approved in 2013 by the FDA for systemic JIA, can also be used. The role of rilonacept is currently under review. Anti-IL-1 treatment may be used to avoid administering corticosteroids or as steroid-sparing agents. Similarly, anti-IL-6 therapy has been shown to be beneficial in controlling systemic symptoms and could be considered in these situations.

For patients with active arthritis (with or without systemic features), a maximum of 1 month of NSAID treatment (with intraarticular corticosteroid injections as needed) was recommended, followed by MTX with adjunctive NSAIDs or intraarticular corticosteroid injections as needed. Recommendations for the treatment of patients with moderate disease activity irrespective of prognostic features after 3 months included either anti-TNF or anti-IL1 medications, with adjunctive NSAIDs or intraarticular corticosteroid injections prescribed as needed. If anti-TNF medications are chosen, patients should be switched to abatacept or anti IL-1 medications

Fig. 103.1 Medical treatment of the oligoarticular subtype of juvenile idiopathic arthritis (JIA). *NSAID trial for 4 to 6 weeks. †Prefer early IATH if knee monoarthritis is present and/or the patient has local complications: contractures, leg-length discrepancy, significant muscle atrophy. IATH, intraarticular triamcinolone hexacetonide; NSAID, nonsteroidal antiinflammatory drug; TNF, tumor necrosis factor.

Fig. 103.2 Medical treatment of polyarticular course of juvenile idiopathic arthritis. *IATH for selected joints. †PO steroids can be considered as bridging medicine or during significant flares. ‡If fails to respond to one anti-TNF agent, consider changing to another, to abatacept, or to tocilizumab. IATH, intraarticular triamcinolone hexacetonide; MTX, methotrexate; NSAID, nonsteroidal antiinflammatory drug; PO, oral; SC, subcutaneous; RA, rheumatoid arthritis; RF, rheumatoid factor; TNF, tumor necrosis factor.

TABLE e103.1
Features of a poor prognosis and levels of disease activity

Type of juvenile idiopathic arthritis	Features of a poor prognosis	Disease activity levels		
		Low disease activity (must satisfy all)	Moderate disease activity (does not satisfy criteria for low or high activity)	High disease activity (must satisfy at least 3)
History of arthritis in 4 or fewer joints	Arthritis of the hip or cervical spine Arthritis of the ankle or wrist AND marked or prolonged elevation of inflammatory markers Radiographic damage (erosions or joint space narrowing on radiography)	One or fewer active joints Normal ESR or CRP Physician global assessment of overall disease activity <3 of 10 Patient/parent global assessment of overall well-being <2 of 10	One or more features greater than low-disease activity level AND fewer than 3 features of high disease activity	Two or more active joints ESR or CRP greater than twice the upper limit of normal Physician global assessment of overall disease activity ≥7 of 10 Patient/parent global assessment of overall well-being ≥4 of 10
History of arthritis in 5 or more joints	Arthritis of the hip or cervical spine Positive rheumatoid factor OR anti-cyclic citrullinated peptide antibodies Radiographic damage (erosions or joint space narrowing on radiography)	Four or fewer active joints Normal ESR or CRP Physician global assessment of overall disease activity <4 of 10 Patient/parent global assessment of overall well-being <2 of 10	One or more features greater than low-disease activity level AND fewer than 3 features of high disease activity	Eight or more active joints ESR or CRP greater than twice the upper limit of normal Physician global assessment of overall disease activity ≥7 of 10 Patient/parent global assessment of overall well-being ≥5 of 10
Sacroiliac arthritis	Radiographic damage in any joint (erosions or joint space narrowing on radiography)	Normal back flexion Normal ESR or CRP Physician global assessment of overall disease activity <4 of 10 Patient/parent global assessment of overall well-being <2 of 10	One or more features greater than low-disease activity level AND fewer than 2 features of high disease activity	ESR or CRP greater than twice the upper limit of normal Physician global assessment of overall disease activity ≥7 of 10 Patient/parent global assessment of overall well-being ≥4 of 10
Systemic arthritis with active systemic features	6-mo duration of significant active systemic disease, as defined by fever, elevated inflammatory markers, or requirement for treatment with systemic glucocorticoids	Disease activity levels (2 levels) Active fever AND physician global assessment of overall disease activity <7 of 10 Active fever AND systemic features of high disease activity (e.g., significant serositis) that result in physician global assessment of overall disease activity ≥7 of 10		
Systemic arthritis with active arthritis	Arthritis of the hip Radiographic damage (erosions or joint space narrowing on radiography)	Four or fewer active joints Normal ESR or CRP Physician global assessment of overall disease activity <4 of 10 Patient/parent global assessment of overall well-being <2 of 10	One or more features greater than low-disease activity level AND fewer than 3 features of high disease activity	Eight or more active joints ESR or CRP greater than twice the upper limit of normal Physician global assessment of overall disease activity ≥7 of 10 Patient/parent global assessment of overall well-being ≥5 of 10

CRP, C-reactive protein; ESR, erythrocyte sedimentation rate.

Fig. 103.3 Medical treatment of systemic juvenile idiopathic arthritis. *Methotrexate, intraarticular corticosteroids and, anti-tumor necrosis factor drugs are less effective for systemic-onset JIA; anti-IL-1 and IL-6 receptor antibody may be more effective. †See text for additional details. ‡May consider intravenous in first week or intermittent intravenous corticosteroid pulses. ASCT, autologous stem cell transplantation; IL, interleukin; IVIG, intravenous immune globulin; NSAID, nonsteroidal antiinflammatory drug; TNF, tumor necrosis factor.

if moderate disease activity persists after 4 months. Similarly, anti-IL-6 therapy has been shown to be beneficial in controlling arthritis and could be considered in these situations.

Intraarticular corticosteroid injections, MTX, and anti-TNF medications appear to be less beneficial than in other subtypes of JIA for both the systemic and arthritis components of the disease. Although intravenous immune globulin (IVIG) is not effective in treating the arthritis component, there may be some benefit, including a corticosteroid-sparing effect, on the systemic component and on macrophage activation syndrome complicating systemic arthritis.

Thalidomide or early treatment with a combination of cyclophosphamide, MTX, and intravenous pulse corticosteroids may be an alternative in unresponsive patients; however, with increased and early use of anti-IL-1 and anti-IL-6 therapy, these medications should not generally be needed. For patients with severe unresponsive systemic and polyarticular JIA, autologous stem cell transplantation (ASCT) may be used as a last resort, although substantial morbidity and mortality are associated with this therapy.

Macrophage activation syndrome

Treatment of JIA-related macrophage activation syndrome includes high-dose intravenous corticosteroid pulses; if this therapy is not rapidly effective, dexamethasone should replace methylprednisolone and cyclosporine should be added. The role of IVIG is unclear, although it is often used. Strong consideration should be given to therapy with etoposide in patients whose disease is progressing rapidly. Recently, anti-IL-1 and perhaps anti-IL-6 therapy have been found to be effective in some patients. Failure of these therapies may require even more aggressive treatment such as antithymocyte globulin or alemtuzumab (Campath).

Enthesitis-related arthritis

Strong evidence is lacking for treating this form of JIA. Open series have indicated that sulfasalazine may be beneficial in these patients, particularly older boys with peripheral oligoarthritis, although in the one small controlled study of patients with this type of arthritis, no significant benefit of sulfasalazine was found. No studies of MTX for this subtype of JIA have been performed. Open series have found anti-TNF therapy to be highly effective.

Active sacroiliac arthritis

The recommendations addressed only anti-TNF medications, and initiation of these medications was recommended in patients with high disease activity

(based on back flexion, ESR/CRP, and physician and patient or parent global assessments) and features of a poor prognosis (radiographic damage in any joint) who failed NSAID treatment, as well as for patients who failed 3 months of MTX or sulfasalazine therapy. Failure of 6 months of MTX or sulfasalazine treatment in patients with moderate disease activity should lead to initiation of a TNF inhibitor.

Psoriatic arthritis

One small series has shown anti-TNF medications to be efficacious for the arthritis of psoriasis but with much less or even a paradoxical effect on the skin disease.⁷ The signs and symptoms of psoriatic arthritis can be the same as those for oligoarticular-onset, polyarticular-onset, and enthesitis-related arthritis, and until other evidence is reported, this disease should be treated like the parallel JIA subset.

Uveitis

Topical therapy for uveitis consisting of corticosteroid drops and mydriatics to prevent posterior synechiae is the treatment of choice. Other local therapies include sub-Tenon corticosteroid injections or long-acting corticosteroid implants. However, it is often hard to wean patients with JIA-related uveitis from topical therapy, and the treatment-related complications of cataract and glaucoma develop in many patients. In such patients, early use of corticosteroid-sparing, disease-modifying therapy, especially MTX, is warranted.⁸ Most patients respond to therapy, and more than 50% attain remission while taking MTX. However, not all patients respond to MTX, and uveitis develops in some even during MTX therapy. To prevent an uveitis flare it is necessary to continue MTX for longer periods (perhaps as long as 2 years) in patients who attained a status of inactive uveitis than in patients who have only arthritis (see later).⁸

Etanercept does not appear to be effective in the treatment of JIA-related uveitis. A small, controlled, double-blind study of 12 patients, as well as uncontrolled studies, did not find etanercept to be effective, and new cases of uveitis or uveitis flares have been reported during etanercept therapy.⁹ For patients nonresponsive to MTX or other immunosuppressive medications, several series have found infliximab and adalimumab to be effective in inducing remission, including discontinuation of topical corticosteroids by most patients.⁸ However, in many patients the effect of infliximab and adalimumab wears off with time. In some patients it is necessary to increase the dose and frequency of infliximab to 20 mg/kg or greater every 4 weeks or to prescribe weekly adalimumab. Some series have indicated that abatacept may be effective for uveitis, including anti-TNF failures.¹⁰ A recent series showed that azathioprine may be effective in the majority of patients

with JIA-related uveitis.¹¹ A small series reported that mycophenolate mofetil was not as effective for JIA-associated uveitis as for other types of uveitis. A preliminary study of high-dose daclizumab, an IL-2 receptor antibody, showed improvement in the majority of patients, but there were substantial safety concerns.¹² For very severe cases, chlorambucil has been used. Cyclosporine does not appear to be very effective for JIA uveitis.

In summary, in patients not responsive to MTX or azathioprine, infliximab and adalimumab appear to be effective, but not etanercept. Abatacept may be used for patients in whom anti-TNF therapy has failed. Cyclosporine does not appear to be very effective. Mycophenolate mofetil has not been adequately studied for JIA-related uveitis. There is still a lack of controlled studies for the treatment of uveitis, but preliminary, still unvalidated consensus outcome measures for these trials have recently been defined.¹³

NONSTEROIDAL ANTIINFLAMMATORY DRUGS

The actual efficacy of NSAIDs (Table 103.4) is unknown because none of the studies (even in the 1970s) were placebo-controlled. In a summary of studies, only 25% to 33% of patients, mainly those with oligoarthritis, showed a significant response to NSAIDs.⁵ A minimum of a 4-week trial of an individual NSAID is necessary to assess its efficacy. Because NSAIDs were not shown to alter the disease course or prevent joint damage, they are used more to treat pain, stiffness, and the fever associated with systemic arthritis. No individual NSAID has been demonstrated to have a clear advantage over others in treating arthritis. It is important to consider the dosing schedule and form of NSAID administration, with a preference for once- or twice-daily dosing to improve adherence to the treatment plan. Suspension preparations are available for naproxen, ibuprofen, meloxicam, and indomethacin, and celecoxib is available as sprinkle capsules. NSAIDs approved by the U.S. Food and Drug Administration (FDA) for use in patients with JIA include tolmetin, naproxen, ibuprofen, meloxicam, and celecoxib (see Table 103.4).

Serious gastrointestinal adverse effects of NSAIDs are rare, although gastrointestinal symptoms do develop in many children. Adverse effects can often be prevented by taking NSAIDs with food, but if not, switching to another NSAID, including cyclooxygenase-2–selective NSAIDs (celecoxib) or using H₂ blockers or proton pump inhibitors, may improve the symptoms. Another important adverse effect is the development of pseudoporphyria, which is most often associated with the use of naproxen in fair-haired, white patients and usually occurs within 2 years of use.⁵ The superficial skin scarring resulting from pseudoporphyria may not resolve for years. Central nervous system adverse effects may occur, including headaches and disorientation, especially with indomethacin. Renal adverse effects, particularly papillary necrosis or tubular function abnormalities, are uncommon in

children but are more frequent during the concurrent use of more than one NSAID. The issue of cardiovascular adverse effects has not been addressed in children.

CORTICOSTEROIDS

Because of many deleterious effects, especially the effect on bone and growth and, in a recent study, a threefold increase in the risk for infection,¹⁴ the use of systemic corticosteroids for JIA should be minimized. No evidence has established that systemic corticosteroids are disease modifying. The main indications for the use of systemic corticosteroids are severe fever, serositis, and macrophage activation syndrome in patients with systemic arthritis. They are also frequently used as a bridging medication until other disease-modifying medications take effect. In some patients, periodic intravenous pulses of corticosteroids (30 mg/kg per dose, maximum of 1 g, usually given for 1 to 3 consecutive days) are used instead of high-dose daily oral corticosteroids, although no controlled studies have shown fewer adverse effects with this modality in children and the effect is short-lived. Calcium and vitamin D supplementation should be used in children receiving systemic corticosteroids.

Evidence of the efficacy of intraarticular injections of corticosteroids is strong, mainly in patients with oligoarthritis. As many as 70% of patients with oligoarthritis do not have reactivation of disease in the injected joint for at least 1 year, and in 40% to 60% of patients this period may be longer than 2 years.⁵ Radiographic and MRI studies have shown a marked decrease in synovial volume after injection without deleterious effects on cartilage. Significantly fewer patients have leg-length discrepancies and joint contractures. Its efficacy is reduced in patients with systemic arthritis. The long-acting agent triamcinolone hexacetonide is more effective and has a longer effect than other forms of injectable corticosteroids, and thus its use is considered standard of care.⁶ Intraarticular corticosteroid injections are also useful for the treatment of temporomandibular joint (TMJ) arthritis. Dexamethasone iontophoresis has been proposed as an alternative to TMJ injection.¹⁵ It may be preferable to use radiologic guidance for joints difficult to access, such as the hip, subtalar, or temporomandibular joints or complex multiple joints such as the wrist.

Few adverse effects are associated with these injections, most often the development of periarticular subcutaneous atrophy or asymptomatic intraarticular calcifications (Fig. 103.4). In some joints, especially the subtalar joint, these effects may occur in as many as half of injections. They may be prevented by injecting small amounts of saline into the joint after the injection and by applying pressure to the injection site. Repeated injections in an individual joint should not be done at less than 3-month intervals; this approach has not resulted in joint or cartilage damage. Patients must be

■ TABLE 103.4 Dosage and special characteristics of nonsteroidal antiinflammatory drugs commonly used to treat juvenile idiopathic arthritis

NSAID	Dose			How supplied	Special characteristics
	mg/kg/d	Maximum, mg	Times per day		
Acetylsalicylic acid	80-100	4000	3-4	Tablet	Need to measure levels, liver enzyme abnormalities, risk for Reye syndrome
Naproxen*	15-20	1000	2	Tablet, suspension	Pseudoporphyria
Ibuprofen*	30-50	2400	3-4	Tablet, suspension	
Indomethacin	1.5-3.0	200	1-2	Capsule, suspension	More gastrointestinal and neurologic adverse events, perhaps more beneficial for fever, pericarditis with systemic arthritis and enthesitis-related arthritis
Tolmetin*	20-30	1800	3	Tablet	
Sulindac	4-6	400	2	Tablet	Fewer renal adverse events
Diclofenac	2-3	200	2	Tablet	
Piroxicam	0.2-0.3	20	1	Tablet	More gastrointestinal adverse effects
Etodolac	10-20	1000	2	Tablet, capsule	
Meloxicam*	0.25-0.375	15	1	Tablet, suspension	
Nabumetone	30	2000	1	Tablet	
Celecoxib*	3-6	200	2	Capsule (can open and use sprinkles)	Use for bleeding disorders, cross-reacts with sulfa allergies

*Approved by the U.S. Food and Drug Administration for the treatment of juvenile idiopathic arthritis.

warned about the risk for infection, although infection is extremely rare when done in aseptic conditions. Occasional cases of aseptic necrosis more likely result from severe underlying disease than from the joint injection itself.

Younger children or children needing multiple joint injections usually require sedation during the procedure. Various types of sedation have been used, including nitrous oxide, various methods of conscious sedation, and general anesthesia.

Fig. 103.4 Radiograph of an ankle joint demonstrating calcifications secondary to corticosteroid injection.

METHOTREXATE

Use of MTX is the cornerstone in the treatment plan for patients with a polyarticular course of JIA (Table 103.5).^{5,6,16} The ACR recommends administering MTX by subcutaneous injection at a dose of 15 mg/m²/wk (maximum of 30 mg).⁶ A large, open, randomized study showed no additional advantage in giving higher doses up to 30 mg/m²/wk.¹⁷

The efficacy of MTX differs by the subtype of JIA, with the greatest efficacy seen in patients with extended oligoarthritis and much lower effects in patients with systemic arthritis.^{5,6} The presence of the 1298C allele in the methylenetetrahydrofolate reductase (*MTHFR*) gene was associated with higher efficacy than was the presence of the A allele,¹⁸ whereas single nucleotide polymorphisms in the 5-aminoimidazole-4-carboxamide ribonucleotide transformylase gene were associated with a lack of response.¹⁹ The radiologic damage progression rate was decreased in two small uncontrolled series, thus suggesting that MTX may exhibit a disease-modifying effect. MTX treatment was also found to improve growth parameters at 1 and 3 years, both for height and for weight, in prepubertal children who responded to MTX.²⁰ Early response to MTX may be predictive of the long-term outcome. Patients with a Pediatric ACR70 response to MTX by 6 months had significantly fewer active joints than did patients with a lesser or no response years later. MTX also improves health-related quality of life.

A recent study showed that about 50% of patients will have flares within 2 years regardless of whether MTX was discontinued 6 or 12 months after attaining a status of inactive disease.²¹ Thus, MTX can be discontinued 6 months after attaining this status. The level of myeloid basic protein 14 was a good measure to predict which patients would experience a flare when MTX was discontinued, thus suggesting that some patients continue to have active disease that is difficult to detect clinically.²¹ Nearly 90% of patients will respond when MTX is restarted. There is no reliable evidence about the preferred method of tapering MTX before discontinuation.

Because food decreases the bioavailability of MTX, it is advised that MTX be taken on an empty stomach. At doses of 10 mg/m²/wk there is no difference in the efficacy of MTX whether administered orally or parenterally.²² MTX at

TABLE 103.5
Dosages and major adverse reactions of other major medications used to treat juvenile idiopathic arthritis

Medication	Dose	Main adverse reactions
Methotrexate	10-15 mg/m ² /wk (parenteral if >12.5 mg/m ²), maximum of 30 mg	Gastrointestinal symptoms, mouth sores, liver enzymes, cytopenia
Sulfasalazine	30-50 mg/kg/day, maximum of 2000 mg, divided into 2 doses	Gastrointestinal symptoms, rash (Stevens-Johnson syndrome), cytopenia
Leflunomide	<20 kg: 10 mg every other day 20-40 kg: 10 mg/day >40 kg: 20 mg/day	Gastrointestinal symptoms, increased liver enzymes
Etanercept	0.8 mg/kg, maximum of 50 mg, SC injection once weekly or 0.4 mg/kg twice weekly	Injection site reaction, upper respiratory symptoms, infections
Adalimumab	<30 kg: 20 mg SC injection every other week ≥30 kg: 40 mg SC injection every other week	Injection site reaction, upper respiratory symptoms, infections
Infliximab	6 mg/kg intravenously at wk 0, 2, and 6 and then every 6-8 weeks (may need to administer every 4 wk as much as 20 mg/kg)	Infusion reactions (allergic), infections
Anakinra	2 mg/kg/day SC injection, maximum of 100 mg	Injection site reaction, upper respiratory symptoms, infections
Rilonacept	Loading dose of 2.2 mg/kg (maximum, 160 mg), then 2.2 mg/kg/week SC injection, maximum of 160 mg	Injection site reaction, upper respiratory symptoms, infections
Canakinumab	4 mg/kg every 4 weeks, SC injection, maximum of 300 mg	Upper respiratory symptoms, infections (particularly pneumococcal), vertigo
Abatacept	10 mg/kg intravenously at wk 0, 2, and 4 and then every 4 wk; maximum of 1000 mg	Infections
Tocilizumab	<30 kg: 12 mg/kg intravenously every 2 wk for systemic arthritis, every 4 wk for polyarthritis ≥30 kg: 8 mg/kg intravenously every 2 wk for systemic arthritis, every 4 wk for polyarthritis	Infections, liver enzymes, hypercholesterolemia
Triamcinolone hexacetonide	For large joints: 1 mg/kg intraarticularly, maximum of 40 mg	Potential for infection, subcutaneous atrophy, intraarticular calcifications

SC, subcutaneous.

greater doses is usually given by subcutaneous or intramuscular injection because oral MTX is not as well absorbed at doses of 12 mg/m² or higher.⁵

MTX should be administered with folic acid, 1 mg/day, or folinic acid, 25% to 50% of the MTX dose, given once weekly the day after MTX. A controlled study of folic acid and a retrospective study of folinic acid found a decreased in the adverse effects of nausea, oral ulcerations, and perhaps liver enzyme abnormalities without decreasing the efficacy of MTX.³

Nausea and other gastrointestinal symptoms are frequent. Strategies to decrease the severity of these events include taking MTX before bed, switching the mode of administration (oral to parenteral), giving MTX in two divided doses (on the same day), and using antiemetics. Many children, especially adolescents, develop a psychological aversion to MTX, which may include anticipatory nausea or behavioral distress before the administration of MTX. This adverse effect may be alleviated by behavioral therapy, including teaching relaxation or self-hypnosis techniques. Although mild elevations in liver enzymes occur frequently throughout the course of treatment, no cases of severe, irreversible liver fibrosis have been reported in patients with JIA.⁵ Routine liver biopsy is not recommended.

Recommendations to monitor for MTX toxicity include complete blood cell counts, liver enzymes, and renal function, although the optimal frequency of testing is unclear.^{5,6} One study reported that tests at 3-month intervals with doses of up to 15 mg/m²/wk detected significant hematologic and liver enzyme abnormalities as often as testing at monthly intervals did. Pulmonary toxicity is very rare in children. Nodulosis has been reported rarely. Very few severe infections have been reported in children. Studies showing the efficacy of mumps, measles, and rubella and varicella vaccines without causing disease flares have resulted in many pediatric rheumatologists modifying previous recommendations that children avoid live vaccinations while taking MTX.²³ Nonlive vaccinations are safe to give, and seasonal influenza vaccine is recommended. Current data do not suggest that the rate of malignancies is greater than in children with JIA not treated with MTX.²⁴ There does not seem to be any long-term impact on fertility.

OTHER DISEASE-MODIFYING ANTIRHEUMATIC DRUGS AND IMMUNOSUPPRESSIVE MEDICATIONS

(Table 103.6, and see Table 103.5)

Most controlled studies in children did not find hydroxychloroquine, oral gold, azathioprine, or D-penicillamine to be significantly effective in the treatment of JIA.⁵ A controlled study showed that sulfasalazine is effective in treating oligoarthritis and polyarthritis,⁵ and earlier introduction of treatment may result in better long-term outcomes. Sulfasalazine may also have disease-modifying effects on radiologic progression.

In a small placebo-controlled study of juvenile spondyloarthritis and in a study in which sulfasalazine was compared with chloroquine for oligoarthritis and polyarthritis, no significant differences were found.⁵ In many open studies, sulfasalazine was most effective in older males with oligoarthritis, which perhaps represents children with enthesitis-related arthritis. Adverse reactions are reported frequently, especially rashes, gastrointestinal symptoms, and leukopenia, and use of sulfasalazine is discontinued in nearly one third of patients. The dose of sulfasalazine is usually increased gradually to 50 mg/kg/day (maximum of 1 g twice daily) to prevent some of these adverse events. Adverse effects may be especially severe in patients with systemic arthritis, with potential for the development of macrophage activation syndrome. Sulfasalazine is contraindicated in patients with porphyria and glucose-6-phosphate dehydrogenase deficiency.

In a controlled study comparing leflunomide with MTX in patients with polyarthritis, significantly more responders were found in the MTX group, although high response rates were also achieved with leflunomide.⁵ Most of the patients responsive to leflunomide maintained their response in a 2-year open-label extension study. No significant differences in adverse effects were found. Leflunomide is used most often in patients who cannot tolerate MTX. Cyclosporine may be more beneficial for controlling fever and reducing corticosteroid doses than for treating arthritis in patients with systemic arthritis and may be especially effective in patients with macrophage activation syndrome. Many adverse effects, especially renal, are associated with cyclosporine.

Two multicenter series found that thalidomide was effective in the majority of patients with refractory systemic arthritis, both for systemic features and for arthritis, with most patients able to significantly reduce their corticosteroid use and obtaining at least a Pediatric ACR30 response.⁵ However, in addition to concern for teratogenicity with thalidomide, careful observation for the development of peripheral neuropathy is necessary. Drowsiness may be significant and require dose reduction or discontinuation.

TABLE 103.6

Efficacy of common medications used to treat juvenile idiopathic arthritis

Medication	Efficacy		
	Persistent oligoarthritis	Polyarticular-course JIA	Systemic-onset arthritis
NSAID	Mild to moderate	Mild	Mild
Intraarticular corticosteroids	Significant	Moderate	Mild to moderate
Methotrexate	Significant	Significant	Mild
Leflunomide	Unknown	Significant	Unknown
Sulfasalazine	Unclear	Moderate	Contraindicated*
Etanercept	Significant	Significant	Moderate
Infliximab	Unknown	Significant†	Moderate
Adalimumab	Unknown	Significant	Unknown
Abatacept	Unknown	Significant	Unknown
Anakinra	Unknown	Mild‡	Moderate to significant
Rilonacept	Unknown	Unknown	Moderate to significant
Canakinumab	Unknown	Unknown	Significant
Tocilizumab	Unknown	Significant	Significant

Mild: effective in up to 25% of patients; moderate: effective in 25% to 50% of patients; significant: effective in more than 50% of patients. For intraarticular corticosteroids, efficacy was measured as benefit for more than 6 months.
Note: Noneffective medications (i.e., hydroxychloroquine, penicillamine, oral gold, azathioprine) or medications not commonly used (cyclophosphamide, intravenous immune globulin, thalidomide, collagen) or not studied in controlled studies in children (rituximab, minocycline) were not included in this table. Evidence is lacking on the utility of medications for the other types of JIA.
*Sulfasalazine is associated with the development of macrophage activation syndrome in patients with systemic disease.
†Was not significantly more effective than placebo in a controlled study.
‡More effective in patients with a systemic-onset arthritis course.
JIA, juvenile idiopathic arthritis; NSAID, nonsteroidal antiinflammatory drug.

BIOLOGIC-MODIFYING MEDICATIONS

Anti-tumor necrosis factor medications

Three anti-TNF medications are currently used for JIA: (1) etanercept, a genetically engineered p75-soluble TNF receptor fused to the Fc domain fragment of human IgG1; (2) adalimumab, a humanized TNF antibody; and (3) infliximab, a murine-based TNF antibody. Newer anti-TNF agents, including golimumab and certolizumab, are currently undergoing trials for polyarthritis.

Etanercept and adalimumab have both been approved by the FDA and European Medicines Agency (EMA) for use in patients with polyarticular-onset JIA after they were found to be effective in two-phase withdrawal studies.^{25,26} Several uncontrolled studies and surveys have suggested that etanercept and infliximab are less effective in patients with systemic arthritis and that the initial response is often not sustained in these patients.⁵ Excellent responses to anti-TNF medications have been reported in uncontrolled studies of patients with juvenile spondyloarthritis.²⁷ These agents usually have a rapid onset of action, but the maximal effect may take several months to achieve.

The dose of etanercept is either 0.4 mg/kg (maximum of 25 mg) given subcutaneously twice weekly or 0.8 mg/kg (maximum of 50 mg) once weekly and is approved from the age of 2 years. Adalimumab is given subcutaneously at a dose of 20 mg every other week in children weighing less than 30 kg and at a dose of 40 mg every other week in children larger than 30 kg and is approved from the age of 4 years. In a controlled study, infliximab did not attain statistical significance in comparison to placebo for the primary outcome, probably because of study design and conduct issues, but it was still effective in the majority of patients.²⁸ Infliximab is given intravenously, initially at a dose of 6 mg/kg at weeks 0, 2, and 6 and then every 8 weeks together with MTX. This dose is associated with fewer adverse effects than 3 mg/kg is, especially infusion reactions and the development of human antichimeric antibodies to infliximab.²⁸

Open-label extension studies of the original pivotal study etanercept cohort for up to 8 years, as well as other registries, have shown continued efficacy in the majority of patients with a polyarticular course, although

MTX was added to the treatment of many of the patients and prednisone to some. More than 65% of patients taking anti-TNF medications have a response greater than the Pediatric ACR50 level. These and other studies have shown a drug survival rate with the first anti-TNF medications of 50% to 60% after 4 years, with the major cause of discontinuation being lack of efficacy and to a lesser degree adverse events, especially with infliximab. Switching to another anti-TNF medication is often effective and safe. However, if the reason for switching is lack of efficacy, the subsequent anti-TNF medications is usually less effective and continued for a shorter period than the first.²⁹ In systemic JIA, switching to (or starting with) anti-IL-1 treatment may be more effective.⁶ Factors associated with an excellent or good response to etanercept are administration at a young age and lower functional disability at the start of treatment. Factors associated with a poor response include systemic JIA and female gender.³⁰ Few data are available on when and how to successfully discontinue anti-TNF therapy, but it appears that approximately 33% of those who discontinue anti-TNF medication after attaining inactive disease status remain disease free for at least 1 year after discontinuation.³¹

Though not specifically studied in the major studies and registries, data suggest that the combination of anti-TNF medications and MTX may be more efficacious than MTX or anti-TNF medications alone, with no significant safety differences, perhaps due to prevention of antibodies formation to the anti-TNF medications.^{5,26}

Initial signs of a disease-modifying effect of anti-TNF medications have been found in uncontrolled studies, including slower radiologic progression, increase in bone strength measured by ultrasound, improved growth velocity independent of the corticosteroid dose and pubertal stage,³² and improved functional status and quality of life.

Adverse effects of anti-TNF medications, though potentially severe, are generally mild and consist of mainly infusion and injection site reactions, upper respiratory infections, and headaches.³³ Overall, the rate of serious adverse effects from anti-TNF medications is estimated to be 0.03 to 0.12 event per patient-year of treatment.³³ Adverse events with infliximab, especially infusion reactions, may lead to discontinuation of the medication more often than with etanercept. Administering infliximab at a dose of 6 mg/kg, as well as premedication with acetaminophen, diphenhydramine, and occasionally hydrocortisone, may prevent or minimize severe infusion reactions. Severe bacterial and varicella infections with complications have been reported, but in general children respond well to standard antibacterial treatment. Autoimmune phenomena have been reported in several children or young adults with JIA, including the development of diabetes mellitus, drug-induced lupus, cutaneous vasculitis, psoriasis, and central nervous system demyelination. Uveitis flare or the new development of uveitis, as well as inflammatory bowel disease, was reported during the use of etanercept, although the causative association has not been proved. Other important adverse events include neurologic symptoms, psychiatric problems, and pancytopenia. Attention should be paid to any family history of demyelinating disease, including consideration of performing screening MRI, and consultation with a neurologist should be obtained if symptoms and signs consistent with demyelination develop.

Rare cases of tuberculosis and histoplasmosis have been reported with the use of anti-TNF medications for JIA. Purified protein derivative skin testing before (and annually during therapy in high-risk patients) anti-TNF therapy is advised in the ACR recommendations for JIA.⁶

At least 48 cases of malignancy, mainly lymphoma, have been reported in children and young adults treated with anti-TNF for JIA and Crohn disease,^{33,34} but in recent studies this rate does not appear to be greater than that children with JIA not treated with anti-TNF medications.^{24,35} Despite these data, the FDA has issued an updated boxed warning highlighting an increased risk for cancer, including lymphoma, leukemia, and melanoma, in children and adolescents who receive anti-TNF agents. Although several small studies suggest that live vaccines may be safe to administer in patients receiving anti-TNF therapy, current recommendations are to avoid them.²³

Abatacept

Abatacept, a selective T-cell costimulator inhibitor (CTLA-4Ig), was found to be effective for JIA with a polyarthritis course in a controlled two-phase withdrawal study involving 190 patients treated with 10 mg/kg (maximum of 1000 mg) intravenously at weeks 0, 2, and 4 and then every 4 weeks.³⁶ Although abatacept was effective in 76% of anti-TNF-naïve patients, nearly 40% of patients who were anti-TNF failures were also considered Pediatric ACR30 responders. Extension studies have shown that abatacept remains effective and improves health-related quality of life for up to 2 years of treatment. In a decision analysis model, abatacept was the most cost-effective biologic agent in achieving a single-patient Pediatric ACR 30 response.³⁷

Adverse effects were generally mild, with rare serious adverse infectious events being reported. Abatacept has been approved by the FDA for use in JIA with a polyarticular course from the age of 6 years. The EMEA, however, approved abatacept only after anti-TNF failure and in combination with MTX.

Anti-interleukin-1 medications

IL-1 has an important role in the pathogenesis of systemic JIA, particularly in early disease. Thus, anti-IL-1 therapy has an increasingly important role in the treatment of systemic JIA. Three anti-IL-1 medications are currently available: anakinra, an IL-1 receptor antagonist; rilonacept, an IL-1 trap (soluble receptor); and canakinumab, a selective IL-1 β antibody.

Several studies, including one controlled study, demonstrated the efficacy of anakinra in patients with systemic JIA, especially for the systemic features of the disease.³⁸ Some studies have suggested that there are two subsets of patients in regard to response to anakinra, with about 50% exhibiting a dramatic response and others having a minimal response.³⁹ It appears that patients with a higher number of active joints respond less well to anakinra, particularly when administered later in the disease process.³⁹ Furthermore, the effect of anakinra appears to dissipate in many patients, and the dose of anakinra often needs to be increased to even higher than 5 mg/kg/day.³⁸ Recent studies have suggested that anakinra may be used as a first-line medication for systemic JIA in patients requiring more than NSAIDs, especially in those with highly active disease and poor prognostic factors as outlined in the ACR JIA treatment recommendations.^{6,40} Anakinra may be effective as part of the treatment of macrophage activation syndrome, but in other patients this syndrome may develop during or after the start of anakinra therapy.⁴⁰ Anakinra has not shown clinically significant effectiveness for polyarthritis JIA.

A small pilot phase 1 study of rilonacept for systemic arthritis showed that it was safe at a dose of 2.2 mg/kg/day administered subcutaneously (maximum of 160 mg), but only about 50% of the patients were responders. In the controlled phase of this trial (not designed primarily for efficacy), no significant differences versus the placebo group were detected.⁴¹ An additional increase in the dose to 4.4 mg/kg/day did not result in improved efficacy. A further large study of rilonacept is nearing completion.

In a phase 2 study, the optimal dose of canakinumab to be further studied was determined to be 4 mg/kg (maximum of 300 mg) given by subcutaneous injection every 4 weeks.⁴² Two controlled phase III studies (a traditional placebo-controlled study and a withdrawal study among responders) showed remarkable efficacy of canakinumab, particularly in patients with fever and rather early disease. The response was seen as early as 15 days following the first injection.⁴³ As a result in 2013 the FDA approved canakinumab for treating systemic arthritis.⁴³

The major adverse effects of anti-IL-1 therapy include injection site reaction (anakinra > rilonacept > canakinumab) and infections, particularly gram-positive (especially pneumococcal) infections.³³ Up-to-date vaccinations, including pneumococcal vaccination, should be ensured in children receiving anti-IL-1 therapy.

Anti-interleukin-6

IL-6 is an important cytokine in the pathogenesis of systemic arthritis, especially for systemic symptoms, thrombocytosis, osteoporosis, and growth retardation. A controlled two-phase withdrawal study of tocilizumab, an antibody to the IL-6 receptor, for systemic arthritis given intravenously at a dose of 8 mg/kg every 2 weeks, with a 48-week open extension, showed a Pediatric ACR30 response rate of 91% and a Pediatric ACR70 rate of 68%.⁴⁴ Flares were significantly increased in the placebo withdrawal group. Another placebo-controlled study in patients with severe and prolonged disease showed similar highly significant improvements, including an open extension for up to 2 years with the ability to significantly reduce corticosteroid use.⁴⁵ A controlled study showed that tocilizumab is also very effective for polyarthritis.⁴⁶ Tocilizumab was approved in 2011 for use in patients from 2 years of age with systemic arthritis by the FDA and EMEA and by the FDA in 2013 for patients with polyarthritis. Serious adverse events have included anaphylaxis, gastrointestinal perforation, and nonopportunistic infections.³³ Hyperlipidemia may also occur. Several deaths took place in the second controlled systemic JIA study, so careful postmarketing safety surveillance is necessary.

Intravenous immune globulin

Two controlled studies did not find IVIG to be effective in treating the arthritis component of systemic and polyarticular JIA.⁵ However, both

studies were small and had insufficient power to detect significant differences. There may be more benefit with IVIG in the first year of the disease and for treatment of the systemic features of systemic-onset arthritis, but this has not been examined in a controlled study. IVIG is often used for the treatment of macrophage activation syndrome at a dose of 2 g/kg, although the evidence to support its use is minimal.

Rituximab

No controlled studies of the use of rituximab (anti-CD20 mature B-cell antibodies) for JIA have been reported. A recent large series (N = 55) showed substantial efficacy for both polyarthritis and systemic JIA refractory to therapy, including infliximab, when rituximab courses were repeated every 24 weeks for up to 96 weeks.⁴⁷

Autologous stem cell transplantation

Evidence that abnormal autoreactive T-cell clones have an important role in the pathogenesis of JIA is substantial. The largest series of patients undergoing ASCT has been reported from the Netherlands, predominately patients with systemic JIA.⁴⁸ Complete drug-free remission was reported in approximately 50% of patients, partial response according to the Pediatric ACR criteria in around 20%, and no improvement in about 20%. The mortality rate was around 10% to 15%, mainly from early post-ASCT infection-associated macrophage activation syndrome (triggered by Epstein-Barr virus, cytomegalovirus, and *Toxoplasma*) and in nonresponsive patients. However, because in longer follow-up many patients experience a relapse of their disease, the long-term effect of ASCT is still not clear.

Many issues regarding patient selection, conditioning protocol, graft preparation, and posttransplant care are still unknown. Improvements in patient selection and pretransplant protocol have resulted in decreased mortality. However, anti-IL-1 and anti-IL-6 medications have decreased the need for ASCT. ASCT must still be regarded as an experimental procedure for selected patients with severe and unremitting disease despite all modern therapies.

STUDIES OF DISEASE-MODIFYING ANTIRHEUMATIC DRUG VERSUS BIOLOGIC COMBINATION THERAPY FOR JUVENILE IDIOPATHIC ARTHRITIS

In the only controlled (open-label) study that included a nonbiologic arm of combination disease-modifying antirheumatic drug (DMARD) therapy it was shown that treatment of patients with early polyarthritis (less than 6 months) with MTX, hydroxychloroquine, and sulfasalazine was superior to MTX monotherapy in attaining a Pediatric ACR75 and inactive disease response, although the combination of infliximab and MTX was superior to both DMARD-only arms.⁴⁹

A controlled, blinded trial of early aggressive therapy (TREAT) for early polyarthritis (less than 1 year) compared treatment with subcutaneous MTX alone (15 mg/m²/wk, maximum of 40 mg) and treatment with a combination of prednisone (weaning over a 4-month period), MTX, and etanercept. Although the study did not attain the primary outcome of a significant difference in the rate of inactive disease at 6 months, there were significant differences in the rate of attaining a Pediatric ACR70 response at 4 months and a status of remission on medication at 1 year. Furthermore, it was shown that the main factor in attaining inactive disease status (for either treatment arm) was initiation of treatment early in the disease course.⁵⁰

MANAGEMENT OF PAIN

Pain, the most common symptom in children with JIA, is an important determinant of physical function and quality of life. Higher pain predicts higher functional disability,⁵¹ and even a modest reduction in pain can result in an improvement in the quality of life of children with JIA.

Control of inflammation is critical to the management of pain. Because multiple factors can lead to pain, specific treatment above and beyond antiinflammatory treatment, including pharmacologic and psychosocial approaches, should be pursued.⁵² Cognitive-behavioral therapy approaches may assist with strategies for coping with pain. Improved fitness may reduce disease activity and pain. Because poor sleep may be a contributing factor to pain, sleep hygiene should be monitored.

Pharmacologic approaches to pain control have traditionally used a “step-up” approach, beginning with acetaminophen and progressing to NSAIDs and opioids. Most pediatric rheumatologists are reluctant to prescribe opioids for fear of their side effects and potential for addiction despite evidence that addiction is not a problem when these medications are used appropriately and prescribed by experienced practitioners in a well-controlled and monitored environment.⁵² The development of localized and diffuse pain syndromes such as fibromyalgia in patients with JIA must also be addressed and treated.

REHABILITATION

The principles of rehabilitation in children with JIA are discussed in detail in Chapter 106. Physical and occupational therapists are integral members of the team and play critical roles in working with the child and family to preserve and improve range of motion and muscle strength. Because of the chronicity of the disease, slow improvements, and pain induced by exercise, adherence with an exercise regimen is often a challenge, and techniques to improve adherence must therefore be used. It was recently shown that this can be done through implementation of an Internet-based program.⁵³ An experienced occupational therapist can be of great benefit in working with the child to find ways to improve function and provide assistive devices, such as ring splints for inflamed fingers and orthotics for inflamed and deformed feet, and to enhance activities of daily living. Customized semi-rigid foot orthotics were found to be superior to both prefabricated “off-the-shelf” shoe inserts and supportive athletic shoes in pain reduction, speed of ambulation, and level of disability in patients with JIA and foot pain.⁵⁴

Children and adolescents with JIA are not as fit as their peer groups and are not as active physically. Multiple reports have demonstrated the safety of increased exercise intensity in most children with JIA, with improved range of motion, increased muscle strength, and some improvements in achieving aerobic fitness. However, high-intensity exercise does not seem to confer added benefits in function or fitness relative to less strenuous exercise.⁵⁵ Hydrotherapy may not offer sufficient benefit to support its routine use.

Approaches to physical activity and participation in sports by children with JIA have recently been published.^{55,56}

MANAGEMENT OF GROWTH RETARDATION

Several factors, most prominently persistent inflammation and the need for corticosteroid treatment, plus early onset of disease, are associated with growth delay. With new treatments resulting in a reduced need for corticosteroids to control symptoms (especially systemic JIA), growth retardation should be less of a problem, although long-term studies are still lacking. Treatment with anti-TNF agents has resulted in improved growth in patients with polyarticular JIA.³² Nevertheless, some patients may still fail to grow adequately; in fact, even patients with oligoarticular JIA treated with just intraarticular corticosteroids may be at risk for growth retardation.⁵⁷ Nutrition assessment and support are necessary to increase caloric intake in patients who fail to gain weight. Some patients may benefit from nighttime tube feeding. Nutrition consultation is also needed for corticosteroid-treated patients on issues such as calorie restriction, adequate calcium and vitamin D, and low sodium intake.

Several studies have shown growth hormone to be of benefit in increasing height growth velocity, even in patients treated with corticosteroids.⁵⁸ Earlier institution of treatment will probably lead to better results. In most studies no significant disease flares were found,⁵⁹ although the authors and others have noticed flares in some patients with disease that is not completely controlled. There are also metabolic concerns, particularly involving lipids, of growth hormone use in patients treated with corticosteroids.

SURGICAL INTERVENTIONS

With improved medical management, the indications for surgical intervention in patient with JIA are fewer; nevertheless, appropriately timed surgery may offer important benefits and improved outcomes in individual patients.

Synovectomy

Removal of inflamed synovial tissue might theoretically be beneficial in children with only one or a few persistently active joints despite appropriate therapy. In general, however, the effect of synovectomy is transient, and thus it should be reserved for specific painful inflamed joints interfering with

function following failure of the medical treatment outlined in the ACR recommendations.⁶ Factors predicting a more sustained response in one study included isolated monoarticular disease, shorter disease duration, and normal acute-phase reactant levels.⁶⁰ A high recurrence rate is seen after synovectomy. Despite excellent or good subjective outcomes, there is frequently no significant improvement in functional ability or range of motion, and complete pain relief is achieved in less than half of the patients. Although there may not be any long-term efficacy, the benefit of arthroscopic synovectomy may be to temporize while systemic medications such as MTX or biologic agents are taking effect.

Epiphysiodesis

With the early institution of more “aggressive” medical management, including intraarticular corticosteroids, the development of leg-length discrepancy and progressive valgus deformity of the knee is less common than in the past. Appropriately timed epiphysiodesis (fusion of the epiphyseal growth plate) plus temporary stapling of the femoral epiphyses, with or without the tibial epiphyses, has resulted in excellent short- and long-term outcomes in correcting leg-length discrepancy with few complications (such as growth plate damage and deep infection).⁶¹ Patients must be monitored closely to avoid overcorrection. This procedure is preferable to surgical epiphysiodesis, which is not reversible. Epiphysiodesis with stapling may also be considered in patients with valgus deformity of the knee, a common knee deformity with JIA. Although the possible benefit in postponing the need for total knee arthroplasty appears to be limited, it may ultimately make the procedure easier by reducing the soft tissue and bony imbalance.

Arthroplasty

Even though current approaches to treatment have led to marked improvements in outcomes, significant joint damage, debilitating pain, and loss of function still develop in a small number of children. It is for these indications that joint replacement surgery may be contemplated. When this is considered, a number of specific issues relevant to pediatric patients must be taken into account. Because of the extensive rehabilitation required and the necessity of adhering to a rehabilitation regimen, the emotional and psychosocial state of the child and family must be assessed to ensure that compliance with the program will be maintained. Special attention must be paid at the time of surgery to joint contractures and soft tissue management, which require release of soft tissues and correction of bony changes. The effect of the disease on growth may result in small bones and difficulty using a standard prosthesis, and therefore custom-made prostheses are often required. Finally, bone quality is often poor because of the underlying disease activity, poor nutrition, immobility, and sometimes corticosteroid therapy. This may result in difficulty using the usually preferred uncemented prosthesis. In general, attempts should be made to delay surgery until the child has stopped growing. However, this must be balanced with the degree of disability and pain. It is important to keep all these principles in mind when considering total joint replacement in patients with JIA.

Total hip and knee arthroplasty results in better improvement in pain than in function.^{62,63} Revisions may be necessary because of aseptic loosening with functional impairment. Prolonged corticosteroid use has a negative

impact on implant survival.⁶² Even in experienced hands, revision surgery is difficult.

Even though outcomes with total knee arthroplasty, as measured by standard assessments, are not as positive as in patients with osteoarthritis, patients report an overall improvement in quality of life and satisfaction with the procedure. A decrease in pain is observed, although improvement in range of motion is not as significant.⁶³ A number of postoperative complications related to poor range of motion of the knee and continuing anterior knee pain may be seen.

When the disease is bilateral, simultaneous procedures should be done if possible. Hip replacement should precede knee replacement to improve the chance of successful rehabilitation. Bilateral combined hip and knee arthroplasty in young patients with JIA has been reported with good success. Reports on shoulder arthroplasty are limited. Pain relief is the major goal of shoulder arthroplasty and can be achieved. A small improvement in range of motion may have a significant impact on function. The results of total elbow arthroplasty are not as satisfactory as with other joints, and it is associated with significant early and late complications.

Surgical treatment of temporomandibular joint deformities

Surgical treatment of TMJ deformities involves a team consisting of a dentist, orthodontist, and craniofacial surgeon, in addition to the rheumatologist. Most case series have reported both improved occlusion and better facial aesthetics postoperatively. Some patients may still be left with TMJ pain, and numbness of the lip, chin, teeth, and gums may develop. A number of different procedures have all been reported to have good outcomes. However, a systematic review was unable to conclude that these procedures were beneficial.⁶⁴

CONCLUSION

The development of new therapies has already markedly increased our ability to effectively treat children with JIA, and the future appears promising, especially for difficult patients with systemic-onset and polyarticular arthritis. However, there is still a lack of evidence-based medicine in the treatment of JIA, especially for enthesitis-related and psoriatic arthritis. Recent sobering studies have shown our inability to induce long-term medication-free remission in most patients, even with modern therapy. Study of the effect of early aggressive therapy on the course of the disease, including the potential use of combination “induction” therapy, has just begun. The long-term disease-modifying effects of MTX and the new “biologic” medications on remission rates, radiologic changes, bone strength, growth, functional capabilities, quality of life, and prevention of surgery are still mostly unknown despite encouraging initial signals of benefit in many of these outcomes. It is necessary to study the long-term adverse effects of these medications, especially if used as combination therapy. Future multicenter controlled studies and postmarketing surveillance with large registries are necessary to address these issues.

Juvenile-onset spondyloarthritis

■ RUBÉN BURGOS-VARGAS

- Juvenile-onset spondyloarthritis is characterized by its association with HLA-B27 as well as by synovitis and enthesitis of peripheral sites in the initial years of disease and, in some patients, the sacroiliac and spinal joints some years later.
- Enthesitis-related arthritis (ERA) and psoriatic arthritis are subgroups of juvenile idiopathic arthritis that are strongly related to juvenile-onset spondyloarthritis (joSpA).
- HLA-B27 and other alleles confer susceptibility to the disease; in some cases, bacterial infections may play a role in the pathogenesis of joSpA and ERA.
- Tumor necrosis factor- α (TNF- α) is prominently expressed in the synovial membrane.
- Patients with joSpA/ERA may have severe short- and long-term functional impairment and persistent disease activity
- TNF- α blockers are likely to be the best treatment of joSpA/ERA.

INTRODUCTION

Juvenile-onset spondyloarthritis represents a group of HLA-B27–associated pediatric rheumatic diseases characterized by the involvement of the synovium and entheses of the peripheral joints in the initial years of disease and, in some patients, the sacroiliac and spinal joints some years later.¹

NOMENCLATURE AND CLASSIFICATION

Juvenile-onset spondyloarthritis (joSpA) and *enthesitis-related arthritis* (ERA) are currently the terms used to describe this group of disorders. The former corresponds to adult-onset terminology and classification, whereas the latter corresponds to one of the seven categories of juvenile idiopathic arthritis (JIA) described by the International League of Associations for Rheumatology (ILAR).² joSpA and ERA differ in that ERA excludes psoriatic arthritis (PsA), reactive arthritis (ReA), and inflammatory bowel disease (IBD) from its boundaries. Thus, the joSpA and ERA concepts are not exactly the same, and not all patients classified as having spondyloarthritis (SpA) or PsA according to several criteria fulfill the ILAR criteria for ERA or PsA.³ Nonetheless, the acronym joSpA/ERA will be used to facilitate comprehension in this chapter despite the fact that some articles refer to SpA and others to ERA.

EPIDEMIOLOGIC ASPECTS

The incidence of joSpA/ERA in American and Canadian children varies from 2.1 per 100,000⁴ to 24.0 per 100,000 children in western Canadian Indians.⁵ The relative proportion of joSpA/ERA in children with all forms of JIA varies from greater than 10% to 36% in different populations.^{6,7} An alternative approach in considering the epidemiology is to examine the proportion that arise in childhood across all ages. When compared with the United States, which has only a very small proportion, around one third of Mexicans, Indians, North Africans, and some Asian groups have an onset before the age of 16 years.⁸

PATHOGENESIS

The etiology of SpA, including joSpA/ERA and adult-onset disease, is still unknown. As suggested in adult SpA, genetic susceptibility and perhaps bacterial infections could be implicated in the pathogenesis of the disease, but the role of mechanical, growth, and developmental factors needs to be investigated.

Genetic factors

joSpA is strongly linked to HLA-B27 across all populations. Chronic SpA develops in 85% of HLA-B27+ children with JIA.⁹ HLA-B27 is linked with specific B27 subtypes in some populations, such as B*2705 in Mexicans¹⁰ and B*2704 in Han Chinese.¹¹ HLA-B27 determines the prevalence of SpA in the general population and in families. Explanations of how HLA-B27 contributes to susceptibility to ankylosing spondylitis (AS) include the arthritogenic peptide hypothesis, the HLA-B27 misfolding and unfolded protein response hypothesis, and the HLA-B27 free heavy-chain and surface homodimer hypothesis.¹² Genome-wide screens in adults have implicated a number of other genetic candidates that may also be relevant to childhood disease. Thus, strong associations have emerged between the genes *RUNX3*, *TNFR1/LTBR*, *IL-12B*, *PTGER4*, *TBKBP1*, *ANTXR2*, *CARD9*, *IL-1R*, *TRADD*, *STAT3*, and *KIF21B*. Of these, *ERAP1* and *IL-23R* have been implicated in pathways such as antigen presentation to interleukin-23 receptor (IL-23R)/type 17 helper T cell (Th17) and tumor necrosis factor (TNF)/Th1 signaling/development.^{12,13} Studies in children have been much less frequent, but interestingly, some of the same candidates, specifically *ERAP1* and *IL-23R*, have been linked to joSpA/ERA and juvenile PsA.¹⁴

Infection

As with their adult forms, both juvenile-onset ReA and other SpAs are linked to bacterial infections. Evidence for joSpA/ERA includes humoral and cellular responses to bacterial constituents such as peptidoglycan¹⁵ and the outer membrane protein of *Salmonella typhimurium*.¹⁶ Likewise, a number of bacteria may trigger disease in patients with ReA and AS, and a variety of bacterial DNA have been found in the synovial fluid cells of patients with joSpA/ERA.¹⁷ Finally, expression of Toll-like receptors 2 and 4 in peripheral blood and synovial fluid cells, which may recognize microbial ligands, is increased in those with joSpA/ERA.¹⁸

HISTOPATHOLOGY

The peripheral joint synovial membrane of patients with joSpA/ERA shows hyperplasia of the lining cells with some CD68 expression and CD163+ macrophages in the sublining layer. There is marked neovascularity with increased numbers of CD146+ endothelial cells,¹⁹ high levels of CD8-activated cells, TNF- β , interferon- γ , IL-2, IL-4, and IL-6.²⁰ Of note, TNF- α is prominently expressed, and most cells express the TNF receptors p55 and p75.²⁰ The metatarsal entheses show scarce inflammatory infiltrates, as well as marked bone proliferation and mucopolysaccharide deposits in soft tissues. The entheses of patients with adult-onset SpA have inflammatory infiltrates in the bone marrow; in fibrocartilage, which also shows increased vascularity and macrophage infiltration; and in the interface between the zones of calcified fibrocartilage and subchondral bone. Studies in animal models have now provided new insight into the pathogenesis of enthesopathy, including the role of bone morphogenetic protein signaling²¹ and the role IL-23 on enthesal resident T-cell receptors.²²

CLINICAL MANIFESTATIONS

The clinical manifestations of joSpA/ERA differ from those of adult-onset SpA in some aspects, particularly AS. Children and adolescents with AS typically have peripheral arthritis and enthesitis in the initial years, with axial symptoms not emerging for 5 to 10 years later, whereas most adults with AS have inflammatory back pain (IBP). Early limb involvement may lead to a greater need for hip replacement than in those with AS commencing in adulthood. This may be a manifestation of more serious peripheral involvement or its longer duration. In general, more childhood-onset cases end in functional classes III and IV, and their mean Bath functional index score is higher.

General aspects

Lower limb peripheral arthritis or enthesitis (or both) occurs in nearly all patients, and their patterns differ very little among specific diagnostic entities (Fig. 104.1). Arthritis and enthesitis may not parallel each other, however, in their severity, duration, and consequences. The distinction between arthritis and enthesitis may be also difficult to determine clinically at some sites, for example, the sacroiliac joints and the feet. Imaging is of major benefit here. Magnetic resonance imaging (MRI) of the spine, sacroiliac joints, and feet (Fig. 104.2) shows hyperintense signals (edema) in the bone, bursa, synovial sheaths, and synovium, consistent with inflammation in short tau inversion recovery (STIR) sequences; structural changes, specifically erosions, bone destruction, enthesophytosis, and ankylosis, may be seen in T1 sequences. Ultrasonography of joints and entheses may provide useful information in patients with active disease, and computed tomography may show structural changes. Radionuclide imaging lacks specificity and does not discriminate inflammation from growing plates.

Peripheral arthritis

Peripheral arthritis is the most frequent sign of joSpA/ERA. At the onset, most patients have unilateral or asymmetric monoarthritis or oligoarthritis involving the knee, midtarsus, and ankle. Less commonly affected are

Fig. 104.1 Involvement of the feet in patients with spondyloarthritis (SpA). (a) Dactylitis of the third digit in a 12-year-old boy with undifferentiated SpA. (b) Diffuse swelling of the tarsal region of an 11-year-old boy with juvenile-onset ankylosing spondylitis. (c) Tarsal swelling, hyperextension of the digits, and keratoderma blennorrhagica in a 16-year-old boy with chronic reactive arthritis. (d) Diffuse swelling of the posterior aspect of the feet, including the ankles and the Achilles, peroneal, and tibial posterior tendons, in a 12-year-old boy with undifferentiated SpA. (Modified from Burgos-Vargas R, Vázquez-Mellado J. *Reactive arthritides*. In: Cassidy JT, Petty RE, editors. *Textbook of pediatric rheumatology*. 5th ed. Philadelphia: Saunders; 2005. p. 604-12; and Burgos-Vargas R. *The juvenile-onset spondyloarthritides*. In: Weisman MH, van der Heijde D, Reveille JD, editors. *Ankylosing spondylitis and the spondyloarthropathies*. St. Louis: Mosby; 2006. p. 94-106.)

the hips, upper extremity joints (shoulders, elbows, and joints of the hands from the wrist to the distal interphalangeal joints), and rarely, the metatarsophalangeal (MTP) and interphalangeal (IP) joints. The course of arthritis typically consists of recurring episodes of monoarthritis or oligoarthritis for 3 to 6 months. In some cases these recurrent episodes of inflammation are followed by some remission, but in others they may lead to severe and persistent polyarthritis. Involvement of the hips and MTP and foot IP joints, as well as some joints of the upper extremities, increases during the course of the disease. Radiographic findings include osteopenia, joint space narrowing, and in some cases, ankylosis. Except for the small joints of the feet and hands in some patients, erosive and destructive changes are rare.

Peripheral enthesitis

Enthesitis and its consequences—osteocartilaginous proliferation and enthesophytosis—are the most specific feature of SpA in children and adults. Enthesitis may occur within the joints (i.e., the sacroiliac joints) and in extraarticular sites (i.e., Achilles tendon and plantar fascia attachments to the calcaneus), and the most frequently involved joints in children are those of the feet (plantar fascia and Achilles tendon attachments to the calcaneus, the fifth metatarsal/cuneal joint, and the functional entheses over the tarsal bones) and then those of the knees (tibial anterior tuberosity and patella), hips (greater trochanter), and pelvis (iliac crest and tuberosity of the ischium); involvement of the upper limb entheses is rare. Enthesitis is associated with pain and sometimes swelling (mainly of the bursae and synovial sheaths) and some reduced mobility. Although some patients have single or very few short episodes of inflammation, others have long episodes of enthesitis. Radiographic changes range from bone overgrowth and enthesophytosis to bone bridging and ankylosis; on the other hand, subcortical bone cysts and erosions may sometimes occur at tendon attachments in peripheral sites, particularly the feet.

Spinal and sacroiliac arthritis

Axial symptoms may accompany disease activity at peripheral sites, particularly severe polyarthritis and enthesitis. The entire spine may be involved, but the thoracolumbar junction and the cervical spine seem to be the most frequently affected. Although children and adolescents with SpA may have back pain, stiffness, and reduced mobility, they usually lack some of the most important characteristics of IBP, specifically, insidious onset, improvement with exercise but not with rest, and pain at night; costosternal and alternating gluteal pain are also rare. In most cases the relevance of axial symptoms increases during the course of the disease, and in most patients AS is diagnosed 5 to 10 years after the onset of peripheral symptoms. Few children and adolescents with prominent axial symptoms and radiographic sacroiliitis fulfill the criteria for AS within 3 years of disease onset. Even though demonstration of sacroiliitis by MRI favors the recognition of adults with preradiographic AS and the early use of TNF blockers, MRI of the sacroiliac joints or the spine has no clear rationale for the same purpose in children and adolescents without axial symptoms. Peripheral symptoms may be so persistent and severe that they should be treated with TNF blockers regardless of axial disease.

Health-related quality of life and functioning

In the absence of successful disease-modifying therapy, only 17% of patients with joSpA/ERA are in remission 5 years after onset²³ and less than 50% by 10 years.²⁴ More than 50% of patients still have active disease 17 years after onset,²⁵ and 60% have functional limitations after 10 years, particularly if they had disease activity for more than 5 years.²⁴ When compared with other JIA subgroups, patients with joSpA/ERA have more pain, as well as higher Childhood Health Assessment Questionnaire scores, poorer physical health, lower physical functioning, and lower health-related quality-of-life scores.²⁶ Patients with juvenile-onset PsA have poorer health than the healthy population and lower 36-item Short-Form Health Survey (SF-36) scores than other JIA subgroups do.²⁷ There are no long-term data on the use of TNF blockers in these patients yet, but it is expected that their prognosis will be substantially improved.

CLINICAL TYPES

Before the 1980s most clinical descriptions referred to juvenile-onset AS and Reiter syndrome; undifferentiated forms became clearly recognized in the early 1980s.^{28,29} Currently, recognition of undifferentiated SpA or joSpA/ERA

Fig. 104.2 T2-weighted fat-suppressed magnetic resonance images of the foot of a 15-year-old boy with ankle swelling and a painful heel (Achilles tendon and plantar fascia) for approximately 6 months. (a and b) Sagittal-lateral views showing synovial fluid effusion in the posterior and anterior ankle joints, the retrocalcaneal bursae, and possibly the fat as well as bone edema of the calcaneus, including the attachments of the Achilles tendon and its continuation to the plantar fascia. (c) Synovial fluid effusion of the ankle joint, edema around the posterior peroneal tendon and extensive edema of the calcaneus on sagittal-posterior views. (d) Coronal views showing extension of the edema to the calcaneus.

is of major importance because of its potential to evolve to more severe forms. Despite the fact that the ILAR JIA classification does not recognize the various types of SpA and that PsA is considered a separate entity, SpA current concepts include all the clinical forms detailed in the following sections.

Undifferentiated spondyloarthritis

Undifferentiated SpA is the most common type of SpA in children and, in a variable proportion of cases, is the earliest form of AS. In the past they were referred as seronegative enthesopathy and arthropathy syndrome²⁰ and as HLA-B27-associated SpA and enthesopathy in childhood,²⁸ among other terms. Today, most patients correspond to the ERA subgroup of JIA. This subgroup may consist of slight or mild conditions entering into full remission or the earliest manifestation of AS and PsA. Approximately 70% to 90% of Canadian and Mexican patients fulfill the criteria for AS approximately 10 years after onset.^{30,31,32} The frequency of polyarthritis, enthesopathy, and IBP is increased in HLA-B27+ children. MRI may reveal subclinical sacroiliitis in a few cases,^{33,34} but there is no clear evidence that MRI-detected sacroiliitis might predict AS. Besides clinical features, HLA-B27 might help in differentiating joSpA/ERA from other JIA subgroups.

Juvenile-onset ankylosing spondylitis

This term refers to AS starting before the age of 16 years. The diagnosis is usually made 5 to 10 years after onset.^{32,35} This situation makes the diagnosis of AS rare before the age of 16. Back complaints in children and adolescents with AS can rarely refer to symptoms of IBP. Radiographic sacroiliitis (Fig. 104.3) is usually found in symptomatic patients. MRI may show acute sacroiliitis. Early-stage AS corresponds to “undifferentiated” SpA. During episodes of disease activity, 5% to 10% of patients have high-grade fever, weight

loss, muscle weakness, fatigue, lymph node enlargement, leukocytosis, or anemia.^{1,32,35} Up to 27% have acute uveitis, and around 80% have nonspecific gastrointestinal manifestations. Cardiovascular manifestations are rare in children,³⁶ and amyloidosis seldom occurs.

Reactive arthritis

In general, this term is restricted to HLA-B27-associated arthritis triggered by *Salmonella*, *Yersinia*, *Campylobacter*, *Shigella*, or *Chlamydia*. Reiter syndrome (an eponym of historical interest) refers to ReA with associated conjunctivitis and urethritis or cervicitis. ReA has occurred in up to 10% of children with yersiniosis,³⁷ 8% with salmonellosis,³⁸ and 12% with *Salmonella typhimurium* phage type 135a infection.³⁹ ReA predominates in the lower extremities,^{40,41} but some patients with *Salmonella* and *Yersinia* ReA have involvement of the hand joints.^{42,43} ReA is usually mild in HLA-B27-children or those with *Yersinia* or *Campylobacter* infection. In contrast, ReA in HLA-B27+ children may evolve into AS. Infection occurs 2 to 4 weeks before the onset of arthritis, but many patients might not report any symptom of infection. Definitive diagnosis requires identification of a triggering infection. Extraarticular manifestations include aphthous stomatitis, conjunctivitis, erythema nodosum, circinate balanitis, keratoderma blennorrhagica, uveitis, urethritis and cervicitis, aortic insufficiency, myocarditis, and pericarditis.⁴⁰⁻⁴³

Juvenile-onset psoriatic arthritis

Juvenile-onset PsA is defined as concomitant occurrence of arthritis and psoriasis in individuals younger than 16 years. According to the ILAR criteria,² the definition may also include patients with either arthritis or psoriasis and dactylitis, nail pitting, or a family history of psoriasis. Diagnostic exclusions include HLA-B27+ boys older than 6 years and the presence of

AS, ERA, sacroiliitis with IBD, Reiter syndrome, or acute anterior uveitis in the patient or a first-degree relative. In contrast to the ILAR classification,² the clinical picture of such a group of patients^{3,44,45} is akin to the SpA concept and PsA classification. Moreover, around 25% of patients with juvenile-onset PsA according to the Vancouver criteria⁴⁶ may not fulfill the ILAR criteria.⁴⁷

The age at onset is usually between 7 and 13 years. Predictors of PsA in children with JIA in the initial 6 months are psoriasis in a first-degree relative, age at onset older than 6 years, and HLA-DRB1*11/12, as well as dactylitis and ankle or toe arthritis.²⁷ Some PsA features are associated with HLA-B27,^{27,46-48} but other HLA alleles are only weakly associated.

Juvenile-onset PsA includes two subpopulations⁴⁶⁻⁴⁸: the younger group is composed mainly of girls with polyarthritis involving the hands, dactylitis, and antinuclear antibodies; the older group includes boys with persistent oligoarthritis, enthesitis, and axial symptoms.⁴⁸ Overall, arthritis is the initial manifestation in 50% of cases, psoriasis in 40%, and their combination in 10%. At onset, 70% of children have oligoarthritis^{27,44}; in a short time, polyarthritis develops in most patients. Small-joint and wrist arthritis differentiates oligo-PsA from oligo-JIA.⁴⁹ Radiographic changes include osteopenia and joint space narrowing, periostitis, erosions, destructive changes, or ankylosis of the hand, cervical spine, and hip joints. MRI might show inflammatory changes in the sacroiliac and spinal joints, as well as in peripheral sites.⁴⁵

Most children have slight or mild skin and nail lesions; 80% have psoriasis vulgaris.^{43,46} Systemic manifestations include chronic iridocyclitis in 15% of patients and fever, pericarditis, IBD, or amyloidosis in a very few cases.^{45,46}

The arthropathy of inflammatory bowel disease: Crohn disease, ulcerative colitis, and indeterminate colitis

In 18% to 30% of patients with Crohn disease and 15% of those with ulcerative colitis the disease starts before the age of 20.⁵⁰ Nine percent of those with Crohn disease and 10% to 20% of those with ulcerative colitis have peripheral arthritis: 1.7% 1 year after the onset of IBD and 4.2% by 10 years.⁵¹ Most patients have peripheral arthritis with or without axial symptoms. Around 50% of children with arthritis associated with IBD have single or recurrent attacks of lower limb monoarthritis or oligoarthritis for less than 4 weeks⁵²; half of such children have simultaneous episodes of

arthritis and gut exacerbations.^{51,52} This type of arthritis does not resemble that of joSpA/ERA, and permanent functional limitations or joint damage do not develop in most patients. In contrast, spondylitis and radiographic sacroiliitis are associated with HLA-B27 in older boys, but this type of arthritis is rare.

Ankylosing tarsitis

This term refers to a set of clinical and radiographic findings, including inflammatory (joint synovitis, enthesitis, tenosynovitis, and bursitis) and proliferative (periostitis, enthesophytosis, and bony ankylosis) changes originally described in HLA-B27-associated joSpA/ERA (Fig. 104.4).⁵³ Some

Fig. 104.3 Grade 3 bilateral sacroiliitis of 6 years' duration in a 14-year-old boy. There is subchondral sclerosis of the iliac bone, joint surface irregularities, which include some erosions on both sides, and joint space narrowing of the hips. (From Burgos-Vargas R. *The juvenile-onset spondyloarthritides*. In: Weisman MH, van der Heijde D, Reveille JD, editors. *Ankylosing spondylitis and the spondyloarthropathies*. St. Louis: Mosby; 2006. p. 94-106.)

Fig. 104.4 Composite images of ankylosing tarsitis in a 16-year-old boy with ankylosing spondylitis of 9 years' duration, complete ankylosis of the tarsal bones, and grade 2 bilateral sacroiliitis. (a and b) Flatfoot and swelling around the ankle. (c to f) T2-weighted fat-suppressed magnetic resonance images showing edema in various tarsal bones, joint spaces (c and d), and soft tissues (e and f) surrounding the tendons of the posterior aspect of the foot on the coronal view (g). Complete ankylosis of the tarsal bones and an enthesophyte at the plantar fascia attachment are seen. (Modified from Burgos-Vargas R. *A case of childhood-onset ankylosing spondylitis: diagnosis and treatment*. *Nat Clin Pract Rheumatol* 2009;5:52-7.)

Fig. 104.5 Short tau inversion recovery (STIR) magnetic resonance image of the sacroiliac joints of a 16-year-old boy with a 3-month history of gluteal pain and a 3-year history of peripheral arthritis and enthesitis before (a) and 14 weeks after (b) treatment with infliximab, 5 mg/kg, at baseline and at weeks 2 and 6. Note edema of the iliac bone and sacrum (line) and part of the inferior quadrant of the sacrum on the opposite side, which cleared after treatment.

of these findings resemble those of the spine and sacroiliac joints in AS. Patients with ankylosing tarsitis have midfoot swelling associated with perimalleolar and Achilles tendon swelling; decreased mobility of the tarsal, ankle, and MTP joints; pes planus; and hyperextension of the MTP joints. Radiographic features include diffuse osteopenia, joint space narrowing, and ankylosis of most tarsal joints, as well as bone cysts, erosions, and osseous proliferation at the enthesis. MRI shows hyperintense signals in bones, synovial sheaths, bursae, and rarely, the joint space. Histopathologic findings include slight inflammatory changes but striking osteocartilaginous proliferation. Ankylosing tarsitis may occur in patients with undifferentiated juvenile-onset SpA and with AS before radiographic sacroiliitis.

THERAPEUTIC APPROACH

Treatment is directed at reducing the intensity and duration of the signs and symptoms of disease and consequently improving health-related quality of life.⁵⁴ There is still no evidence that any treatment might halt disease progression.

NSAIDs provide symptomatic relief for most patients with mild symptoms. Oral and intraarticular glucocorticoids may be beneficial in patients with moderate or severe disease activity who do not respond to NSAIDs. Most patients receive sulfasalazine, which has shown some efficacy,⁵⁵ or MTX without any clear evidence of efficacy in patients with joSpA/ERA arthropathy or enthesopathy. It seems that these drugs may improve psoriasis, anterior uveitis, and keratoderma blennorrhagica in some patients.

The use of TNF- α blockers represents the most significant advance in therapy for joSpA/ERA, including AS and PsA.⁵⁶⁻⁶⁰ The antiinflammatory effect of etanercept, infliximab, and adalimumab is clearly noticed within the first few weeks of treatment, and long-term administration of these drugs provides sustained relief. However, retrospective studies of joSpA/ERA suggest that fewer patients evolve to inactive disease and, moreover,

discontinuation of TNF blockers seems to be less successful than in other JIA subgroups.⁶⁰⁻⁶³ MRI of peripheral and sacroiliac joints may also show significant improvement of inflammation with TNF- α blockers (Fig. 104.5). TNF- α blockers have been considered safe and well tolerated. The U.S. Food and Drug Administration (FDA) issued a boxed warning* highlighting the increased risk for cancer, including lymphoma, leukemia, and melanoma, in children and adolescents who receive anti-TNF agents. However, because of the relatively rare occurrence of these cancers, the limited number of pediatric patients treated with TNF blockers, and the possible role of other immunosuppressive therapies used concomitantly with TNF blockers, the strength of the association between TNF blockers and development of a malignancy cannot be fully characterized.⁶⁴

Lower limb involvement may affect walking, climbing stairs, and the standing position. Those with axial involvement may have an important reduction in spinal mobility and chest expansion. Therefore, patients should be enrolled in physical and occupational therapy programs in which rest, dynamic splints, and exercises for muscle strength and stretching are implemented on an individual basis. Surgical modalities such as soft tissue release, synovectomy, tendon repair, arthroplasty, and joint replacement may be indicated for some forms of hip, knee, and MTP disease.

joSpA may profoundly harm the quality of life of children and adolescents and therefore their transition to adulthood. Thus, it is important to consider the psychological, educational, and socioeconomic aspects of the patient's life. Disease activity and, later, disease damage may affect these individuals' social life, including personal and family activities, education, and jobs.
